## THE INTERNATIONAL INSTITUTE OF AGRICULTURE

---

### ORIGIN OF THE INSTITUTE AND SUMMARY OF THE INTERNATIONAL TREATY

The International Institute of Agriculture was established under the International Treaty of 7 June 1905, which was ratified by forty governments. Twenty-two other governments have since adhered to the Institute,

It is a Government institution in which each country is represented by delegates. The Institute is composed of a General Assembly and a Permanent Committee.

The Institute, always confining its attention to the international aspect of the various questions concerned, shall :

(a) collect, study and publish as promptly as possible, statistical, technical, or economic information concerning farming, vegetable and animal products, trade in agricultural produce, and the prices prevailing in the various markets ;

(b) communicate the above information as soon as possible to those interested ;

(c) indicate the wages paid for farm work ;

(d) record new diseases of plants which may appear in any part of the world, showing the regions infected, the progress of the diseases, and if possible, any effective remedies ;

(e) study questions concerning agricultural co-operation, insurance and credit from every point of view ; collect and publish information which might prove of value in the various countries for the organization of agricultural co-operation, insurance and credit ;

(f) submit for the approval of the various governments, if necessary, measures for the protection of the common interests of farmers and for the improvement of their condition, utilizing for this purpose all available sources of information, such as resolutions passed by international or other agricultural congresses and societies, or by scientific and learned bodies, etc.

# PERMANENT COMMITTEE OF THE INTERNATIONAL INSTITUTE OF AGRICULTURE

*President : His Exc. EDOARDO PANTANO, Senator, Delegate of Italy.*

*Vice-President : M. LOUIS-DOP, Delegate of France.*

*List of the Delegates to the Permanent Committee :*

1	ARGENTINA .....	I	Prof. TOMÁS AMADEO
2	AUSTRIA .....	IV	
3	BELGIUM .....	IV	P. DE VUYST, Director-General, Ministry of Agriculture.
4	BELGIAN CONGO .....	V	P. DE VUYST.
5	BRAZIL .....	I	D. DE CAMPOS, Commercial Attaché to the Embassy.
6	BULGARIA .....	III	G. RADEFF, Minister Plenipotentiary.
7	CHILE .....	II	E. VILLEGAS, Minister Plenipotentiary.
8	CHINA .....	I	TCHOU YIN, Secretary to the Legation.
9	COLOMBIA .....	V	Prince RUFO RUFFO.
10	COSTA-RICA .....	V	
11	CUBA .....	V	Dr. F. F. FALCO.
12	CZECHOSLOVAKIA.....	III	
13	DENMARK .....	IV	H. DE KAUFFMANN, Minister Plenipotentiary.
14	ECUADOR .....	V	
15	ETHIOPIA .....	V	Prof. A. MAURI, Member of Italian Chamber of Deputies.
16	EGYPT .....	II	Sir THOMAS H. ELLIOTT, Bart., K. C. B.
17	FINLAND .....		
18	FRANCE .....	I	LOUIS-DOP, Vice-President of the Institute.
19	ALGERIA .....	III	LOUIS-DOP.
20	FRENCH WEST AFRICA	IV	LOUIS-DOP.
21	INDO-CHINA .....	V	LOUIS-DOP.
22	MADAGASCAR .....	V	LOUIS-DOP.
23	MOROCCO .....	III	LOUIS-DOP.
24	TUNIS .....	V	LOUIS-DOP.
25	GERMANY .....	I	Dr. MEHRRENS, Councillor of State.
26	GT. BRITAIN & IRELAND	I	Sir THOMAS H. ELLIOTT, Bart., K. C. B.
27	AUSTRALIA .....	III	Sir THOMAS H. ELLIOTT, Bart., K. C. B.
28	BRITISH INDIA .....	II	Sir THOMAS H. ELLIOTT, Bart., K. C. B.
29	CANADA .....	II	Sir THOMAS H. ELLIOTT, Bart., K. C. B.
30	NEW ZEALAND .....	IV	Sir THOMAS H. ELLIOTT, Bart., K. C. B.
31	UNION OF SOUTH AFR.	IV	Sir THOMAS H. ELLIOTT, Bart., K. C. B.
32	GREECE .....	IV	D. G. METAXAS, Minister Plenipotentiary.
33	GUATEMALA .....	V	J. MONTEFIORE, Consul General.
34	HAITI .....		
35	HUNGARY .....	I	
36	ITALY .....	I	His Exc. EDOARDO PANTANO, Senator, Presid. of the Ins.
37	ERITREA & IT. SOMALIA	IV	Prof. G. DE MICHELIS, Gen. Commissioner of Emigration.
38	TRIPOLI AND CIRENAICA	IV	Count EDOARDO SODERINI.
39	JAPAN .....	I	MINORU FUJII, Secretary to the Embassy.
40	LATVIA .....	V	Dr. M. WALTERS, Minister Plenipotentiary.
41	LUXEMBOURG .....	V	P. DE VUYST
42	MEXICO .....	III	
43	MONTENEGRO .....	V	G. VOLPI, Minister Plenipotentiary.
44	NETHERLANDS .....	IV	Dr. J. J. L. VAN RIJN, Commercial Attaché to the Legat.
45	DUTCH EAST INDIES.....	IV	Dr. J. J. L. VAN RIJN.
46	NICARAGUA .....	V	V. E. BIANCHI, Consul General.
47	NORWAY .....	IV	A. FJELSTAD, Counsellor to the Agricultural Department.
48	OTTOMAN EMPIRE.....	I	Dr. MEHMED DJEMIL Bey.
49	PARAGUAY .....	V	
50	PERSIA .....	V	A. DEL GALLO, Marquis of ROCCAGIOVINE.
51	PERU .....	V	Prof. E. P. MOLINATTI.
52	POLAND .....	IV	B. JANISZOWSKI, Consul General.
53	PORTUGAL .....	IV	EUSEBIO LEÃO, Minister Plenipotentiary.
54	ROUMANIA .....	I	N. DIANU, Counsellor to the Legation.
55	RUSSIA .....	I	His Exc. G. ZABIELLO, Consul General.
56	SAN MARINO .....	V	His Exc. L. LUZZATTI, Minister of State.
57	KINGDOM OF THE SERBS, CROATS AND SLOVENES.	III	C. SCOTTI, Consul General.
58	SPAIN .....	I	FRANCISCO BILBAO Y SEVILLA, Agricultural Engineer.
59	SWEDEN .....	IV	Baron C. N. D. DE BILDT, Counsellor to the Legation.
60	SWITZERLAND .....	IV	GEORGES WAGNIERE, Minister Plenipotentiary.
61	UNITED STATES .....	I	
62	URUGUAY .....	V	ENRIQUE J. ROVIRA, Consul.

*Secretary General : Prof. CARLO DRAGONI.*

*In quoting articles, please mention this REVIEW.*

PERIODICAL PUBLICATIONS REVIEWED BY THE BUREAU OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES . . . . .	page	IX
WEIGHTS, MEASURES AND MONEY OF THE VARIOUS COUNTRIES WITH THEIR ENGLISH EQUIVALENTS . . . . .	page	XXXIX

### ABSTRACTS

## AGRICULTURAL INTELLIGENCE.

### I. — GENERAL INFORMATION.

- HYGIENE.** — 1. The Effect of a Variation in Milling on the Digestibility of Wheat Flours — 2. The "Bacteriophagous" Microbe  
**AGRICULTURAL EXPERIMENTATION.** — 3 New Institutes for Agricultural Experiment in Italy.  
**EXHIBITIONS, MEETINGS, CONFERENCES** — 4 The International Congress of Household Economy Instruction, Paris, 18-21 April 1922

### II. — CROPS AND CULTIVATION.

#### a) GENERAL.

- AGRICULTURAL METEOROLOGY** — 5 Information concerning the Amazon Region, Brazil. — 6 Influence of Climate on the Fixity of Hybrids from the Standpoint of the Segregation of Characters in the Second Generation  
**SOIL PHYSICS** — 7 Researches on the Specific Gravity of certain Soil Constituents from the Point of View of the Fineness of the Soil Particles — 8 Effect of Temperature upon the Absorbent Properties of Soils — 9 Relation between the Nitrogen Content of the Soil and the Yield of Indigo in India  
**METHODS OF CULTIVATION** — 10 "Taungya" Cultivation in the Shan States, Burma, and Methods of Soil Treatment recommended  
**MANURES AND MANURING** — 11 Experiments in Liming in the United States and in Canada — 12 The Present Condition of the Superphosphate Industry in Japan — 13 Relation of Organic Matter and the Feeding Power of Plants to the Utilisation of Rock Phosphate — 14 The Effect of Basic Slag upon Grassland and the subsequent Crops — 15 Results of Manuring with Superphosphate on the Yield and Quality of Indigo in India. — 16 Effect of Phosphate Fertilisers in Conjunction with Green Manures, upon Spring Cereals in India — 17. Assimilability of Organic Nitrogenous Compounds. — 18. The Influence of Certain Fertiliser Salts on the Growth and Nitrogen Content of some Leguminous Plants — 19 Carbonication of Plants by Combustion Gases.

#### b) SPECIAL

- AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS** — 20 A Systematic Catalogue of the Plants cultivated in Spain (Species and Varieties) and of the Principal Species of Trees. — 21 "Arroz bravo", a Wild Rice in the Interior of Brazil. — 22 Composition of Californian Citrus Fruits. — 23. A Study of Nitrogen and Root Space as Factors limiting the Yield of Maize in Egypt — 24 Observations on the Growth of Maize in Egypt.  
**PLANT BREEDING** — 26 Study of Barley Hybrids, especially from the Standpoint of Fixity of the Segregation of Characters in the  $F_2$ . — 27. Studies in Linkage Relations in Maize made in the United States. — 28 Type and Variability in Kafir (*Andropogon Sorghum*). — 29. The Interesting Relation between the Appearance of the Globe Mutant in *Datura*

# PERMANENT COMMITTEE OF THE INTERNATIONAL INSTITUTE OF AGRICULTURE

*President : His Exc. EDOARDO PANTANO, Senator, Delegate of Italy.*

WEIGHTS, MEASURES AND MONEY OF THE VARIOUS COUNTRIES WITH THEIR ENGLISH EQUI- VALENTS . . . . .	page XXXIX

### ABSTRACTS

## AGRICULTURAL INTELLIGENCE.

### I. — GENERAL INFORMATION.

- HYGIENE — 1 The Effect of a Variation in Milling on the Digestibility of Wheat Flour —  
2. The "Bacteriophagous" Microbe  
AGRICULTURAL EXPERIMENTATION — 3 New Institutes for Agricultural Experiment in  
Italy  
EXHIBITIONS, MEETINGS, CONFERENCES — 4 The International Congress of Household Eco-  
nomy Instruction, Paris, 18-21 April 1922

### II. — CROPS AND CULTIVATION.

#### a) GENERAL

- AGRICULTURAL METEOROLOGY — 5 Information concerning the Amazon Region, Brazil. —  
6 Influence of Climate on the Fixity of Hybrids from the Standpoint of the Segregation  
of Characters in the Second Generation  
SOIL PHYSICS — 7 Researches on the Specific Gravity of certain Soil Constituents from the  
Point of View of the Fineness of the Soil Particles — 8 Effect of Temperature upon  
the Absorbent Properties of Soils — 9 Relation between the Nitrogen Content of the  
Soil and the Yield of Indigo in India  
METHODS OF CULTIVATION — 10 "Taungya" Cultivation in the Shan States, Burma,  
and Methods of Soil Treatment recommended  
MANURES AND MANURING — 11 Experiments in Liming in the United States and in Can-  
ada — 12 The Present Condition of the Superphosphate Industry in Japan —  
13 Relation of Organic Matter and the Feeding Power of Plants to the Utilisation of  
Rock Phosphate — 14 The Effect of Basic Slag upon Grassland and the subsequent  
Crops — 15 Results of Manuring with Superphosphate on the Yield and Quality of  
Indigo in India. — 16 Effect of Phosphate Fertilisers in Conjunction with Green Man-  
ures, upon Spring Cereals in India. — 17 Assimilability of Organic Nitrogenous Com-  
pounds. — 18. The Influence of Certain Fertiliser Salts on the Growth and Nitrogen  
Content of some Leguminous Plants — 19 Carbonication of Plants by Combustion  
Gases

#### b) SPECIAL

- AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS — 20 A Systematic  
Catalogue of the Plants cultivated in Spain (Species and Varieties) and of the Principal  
Species of Trees. — 21 "Arroz bravo", a Wild Rice in the Interior of Brazil. — 22 Com-  
position of Californian Citrus Fruits — 23 A Study of Nitrogen and Root Space as  
Factors limiting the Yield of Maize in Egypt — 24 Observations on the Growth  
of Maize in Egypt.  
PLANT BREEDING — 26 Study of Barley Hybrids, especially from the Standpoint of Fixity  
of the Segregation of Characters in the  $F_2$ . — 27. Studies in Linkage Relations in Maize  
made in the United States — 28 Type and Variability in Kafir (*Andropogon Sorghum*).  
— 29. The Interesting Relation between the Appearance of the Globe Mutant in *Datura*

## CONTENTS

- Stramonium* and the Behaviour of the Chromosomes. — 30 Number of Chromosomes in various Species of *Lactuca* — 31 The "Akala" (*Rubus Macraei* Gray), an Endemic Hawaiian Raspberry and the Possibilities of its Improvement by Hybridisation and Selection. — 32. "Tangelolo", a New Citrus Fruit obtained by Crossing the "Sampson Tangelo" with *Citrus decumana*
- SEEDS.** — 33 Determination of the Origin of Linseed on the Market.
- CEREALS AND PULSE CROPS** — 34 Possibility of growing Wheat in the State of Piauh, Brazil — 35. Kanota: An Early Oat introduced into Kansas, United States. — 36. Varieties of Rice tested in 1921, in the Experiment Field of the "Granja arrocerá" of Sueca, Valencia, Spain — 37 Moki Lima Beans (*Phaseolus lunatus*) in Egypt. — 38. Lentil-Growing in Brazil
- STARCH CROPS** — 39 Yam Culture (*Dioscorea* spp.), in Porto Rico
- FORAGE CROPS, MEADOW AND PASTURES** — 40 The Chemical Composition and Yield of Forage Maize cut at different Stages, in Hungary — 41. Experiments in growing Italian Ryegrass (*Lolium italicum*), in Brazil — 42 Cultivation of *Phalaris bulbosa* in Uruguay. — 43. *Phragmites communis* as a Cattle Feed in Germany — 44 Lucerne in North Africa. — 45 Cultivation of Sulla in Eritrea — 46 *Atriplex semibaccata*, a Good Forage Plant for Chile — 47 Pasturage in the Fiji Islands.
- FIBRE CROPS.** — 48 Cotton Cultivation in Korea
- PLANTS YIELDING OILS, DYES, TANNINS, ETC.** — 49 The Past and Future of Olive Growing in Libya — 50 Notes on Indigo, Effect of Phosphate Manures and general Conditions affecting the Yield and Quality of Seed in India
- RUBBER, GUM AND RESIN PLANTS** — 51. Notes on Alternate Tapping of Hevea in Indo-China. — 52 Possibility of cultivating the Camphor Tree at Porto Rico
- STIMULANT, AROMATIC, NARCOTIC, AND MEDICINAL PLANTS** — 53. A New Method of Harvesting Coffee. — 54 The Santalaceae and Sandal Wood: Distribution and Uses. — 55. Clove Oil from Clove Stems (*Eugenia Caryophyllata*) in the Islands of Zanzibar and Pemba. — 56 Notes on Virginian and Turkish Tobaccos: Modes of Production, Supply and Demand with special Reference to Rhodesia and Other Provinces of South Africa. — 57. White Burley Tobacco in Canada
- ARBORICULTURE** — 58 The "Pejabaye" (*Gouletma utilis*). Fruit with High Food Value, in Costa Rica.
- FORESTRY** — 59 Forestry in China — 60 The Forests of the United States as a Source of Liquid Fuel Supply

## III — LIVESTOCK AND BREEDING.

### a) GENERAL.

- CATTLE HYGIENE** — 61 International Conference for Defence against Epizootic Disease, Paris, May-June 1921 — 62 "Mexican Whoiled Milkweed" (*Asclepias Mexicana*), a Plant Poisonous to Live Stock in the United States — 63 Contribution to the Study of the Tuberculosis of Domestic Animals in reference to Human Tuberculosis. — 64 Detailed List of Horse Strongyles in the Punjab, India — 65 Resistance of Various Breeds of Donkey to Skin Disease Observations made in Tunis — 66. The Piroplasmosis of Indo-China. — 67. Diseases of Live Stock in Fiji — 68 Piroplasmosis due to *Theileria parva* in North Africa — 69. Note on the Trypanosomiasis of the Dromedary (Debab) — 70 Critical Study of some of the Nematodes of Camels in India — 71 The Animal Parasites of Foxes with special Reference to some Species of Hookworms (*Uncinaria*) — 72. Cystoid Forms of *Taenia scruiis* in the Psoatic and Dorsal Muscles of Wild Rabbits and Hares in Sardinia
- ANATOMY AND PHYSIOLOGY.** — 73 Researches on the Rate of Growth of the Dairy Cow. Extra-Uterine Increase in Weight — 74 Lactic Secretion in an Unmated Mule.
- FEEDING** — 75 Experiments made in Egypt on the Digestibility of Bersim (*Trifolium alexandrinum*) — 76 Brazil Beans, or "Mulatinos", a Variety of *Phaseolus vulgaris*, as a Stock Feed Researches and Experiments made in Germany — 77 The Concentrated Food "Fruges Lin", or "Nutritivo Squassi", in Feeding Cattle: Experiments made in Italy — 78 Microscopic Examination of Flour from the Common Reed.
- ANIMAL GENETICS** — 79 A Mendelian Experiment in crossing Aberdeen-Angus and West

- Highland Cattle: Experiments made in Great Britain. — 80. Zoometric Data for the Pure-Bred Foal at different Ages. Measurements taken in the United States.
- BREEDING. — 81. The Stock-Breeding Institute of Sidi-Tabet, Tunisia. — 82. Live Stock Industry in Fiji. — 83. The Live-Stock of Italian Somaliland; Census of February 1, 1921.
- CATTLE. — 84. The Val di Chiana (Tuscany) Breed of Cattle and its Improvement. — 85. Comparison between the Milk Yield of Young Cows and Mature Cows. Researches made in the United States. — 86. Methods adopted for improving Live-Stock in Tunis. — 87. Cattle Rearing in Fiji.
- POULTRY. — 88. Turkey Rearing in Sologne, France. — 89. Shortening the Incubation Period by Exposing Eggs to Radium Emanation: Experiments made in Austria. — 90. The Comparative Efficacy of Animal and Plant Protein in stimulating Egg Production. Duck Feeding Experiments in the Philippines.
- SERICULTURE. — 91. Silkworm-Breeding in Tripolitania. — 92. Introduction of Sericulture into Columbia. — 93. The Possibilities of rearing the Eri Silkworm, *Attacus ricini*, in Egypt.

#### IV. — FARM ENGINEERING.

- AGRICULTURAL MACHINERY AND IMPLEMENTS — 94. The Power Farming Trial Week at Ondes, Haute Garonne, France — 95. Trials of a Tractor running on Poor Gas, in France. — 96. Mechanical Flax-Gatherers at the Show held at Wattignies-lez-Lille, France. — 97. Wind-Mill with Coupled Wheels.

#### V. — RURAL ECONOMICS.

98. Cost of Producing One Quintal of Grapes in the District of Asti, Piedmont.

#### VI — AGRICULTURAL INDUSTRIES.

- INDUSTRIES DEPENDING ON PLANT PRODUCTS — 99. Extraction of Grape-Pip Oil by means of the Dutch "Tordoir". — 100. Paraffin from Colza-Oil. — 101. Development of Indigo Industry in India and Nature of Changes occurring during Extraction.
- INDUSTRIES DEPENDING ON ANIMAL PRODUCTS — 102. Changes in the Composition of Sheep's Milk during the Lactation Period. Experiments made in Hungary.
- AGRICULTURAL PRODUCTS: PRESERVING, PACKING, TRANSPORT, TRADE. — 103. Live Stock Industry in Fiji. — 104. The Turkey Industry in Sologne, France.

### PLANT DISEASES.

#### II. — DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

105. A Transmissible Mosaic Disease of Lettuce in the United States, especially in Florida. — 106. Dry Gummosis of Citrus Trees in Sicily.

#### III. — DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

##### a) GENERAL.

- GENERAL INFORMATION. — 107. Fungi of Macedonia. — 108. New Studies on the Life-History of "Malvacea Rust" (*Puccinia Malvacearum*). — 109. On the Germination of the Zoospores of Vine "Mildew".
- RESISTANT PLANT. — 110. Kanota Oat Var. resistant to Rust and Smut in Kansas, U. S. — 111. — "Formosa", Spanish Vine not attacked by "Mildew" in Italy.
- MEANS OF CONTROL. — 112. Copper, the Active Principle in Sprays. — 113. Experiments in the Use of Salts of Mercury in the Anticryptogamic Treatment of Seeds.

## b) SPECIAL

**PARASITIC DISEASES OF DIFFERENT PLANTS.** — 114 *Aspergillus varians*, a Mucedinea parasitic on Maize, in Italy. — 115. *Macrophoma flaccida*, a Deuteromycete causing Deterioration in Dried Grapes in the Marches, Italy. — 116 On the Cankorous Tumours of *Diplodina Castaneae* observed on the Chestnut-Tree in France. — 117. A Wide-Spread Attack of *Rhytisma acerinum* observed on the Leaves of the Common Maple, in the Marches, Italy. — 118. *Cenangium pinophilum* n. sp. Discomycete Injurious to *Pinus ponderosa* and *P. contorta*, in the States of Idaho, Washington and Montana. — 119. The White Pine Blister Rust (*Cronartium ribicola*) found in Pennsylvania. — 120. *Trametes Pini* in Old Stands in the Joux Valley, Switzerland. — 121. *Phomopsis Pseudotsugae*, Deuteromycete Parasite of *Larix leptolepis* and *Tsuga Albertiana*, in Scotland.

## V. — INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

**GENERAL INFORMATION** — 122. On the Subject of Myrmecophily. — 123. The Effect of Phylloxera on the Quality of Grapes.

**RESISTANT PLANTS.** — 124. Wood of *Pterocarpus*, Resistant to White Ant.

**MEANS OF CONTROL** — 125 *Drosophila rubrostriata* and *Phora Chlorogastra*, Diptera recorded as Parasites of the White Cabbage Butterfly (*Pteris brassicae*), in France, 126. The Introduction into France of *Aphelinus mali*, the American Parasite of the Woolly Aphis of the Apple-Tree (*Eriosoma lanigera*) — 127. Economy in Hydrocyanic Fumigation

## b) SPECIAL.

**INSECTS, ETC., INJURIOUS TO VARIOUS CROPS** — 128. Insects Injurious to the Lima Bean (*Phaseolus lunatus*) in Egypt. — 129. An Undetermined Dipteron Injurious to Lucerne, in France. — 130. *Paria canella* The Strawberry Rootworm in California. — 131. On the presence of the Coccid, *Icerya purchasi* in the Neighbourhood of Paris. — 132. *Icerya purchasi* in Hérault — 133 *Agrilus foveicollis*, Coleopteron Injurious to Roses in Bulgaria — 134. *Laspeyresia molesta*, a Microlepidopteron Injurious to the Peach and other Fruit Trees reported in Liguria Italy

EDITORIAL STAFF OF THE BUREAU OF AGRICULTURAL INTELLIGENCE  
AND PLANT DISEASES.

Chief of Bureau: Dr. JULES-MICHEL SAULNIER.

## Editors:

Dr. GUIDO BORGESANI, Chief Rédacteur.  
Prof. GIULIO TRINCHIERI, Chief Rédacteur.  
Prof. GIROLAMO AZZI, Chief Rédacteur.  
THÉODORE BRÉLER, Lic. ès Sc. phys. et mat.,  
Chief Rédacteur.

Dr. FRANCESCA DORIO.  
FRÉDÉRIC SORO, Ing. Agr.  
MARGARITE L. YEO, Dipl. Hort. Sc.  
Oxford & Reading.

The Bureau assumes no responsibility with regard to the opinions and the results of experiments outlined in this Review.

The Editor's notes are marked (Ed.).

# WEIGHTS, MEASURES AND MONEY OF THE VARIOUS COUNTRIES WITH THEIR ENGLISH EQUIVALENTS.

1 Archine (Russia)	=	27.99961 inches
1 Ardeb (Egypt)	=	5 44435 bushels
1 Ardeb of wheat (Egypt)	=	2.95264 cwt.
1 Ardeb of hulled maize (Egypt)	=	2 75580 cwt.
1 Ardeb of barley (Egypt)	=	2.36211 cwt.
1 Ardeb of undecorticated rice (Egypt)	=	5.72812 cwt.
1 Ardeb of decorticated rice (Egypt)	=	3 83813 cwt.
1 Arpent (Canada)	=	0.84501 acres
1 Are [100 square metres]	=	107 63915 square feet
1 Arroba (Brazil)	=	33 06951 lbs
1 Arroba (Cuba, Guatemala, Paraguay, Peru)	=	25 35841 lbs
1 Arroba (Mexico)	=	25.36657 lbs
1 Bale of cotton (Brazil)	=	396.83415 lbs
1 Bale of cotton (United States)	=	4 46431 cwt (gross wt.)
1 " " " " "	=	4 26788 cwt (net wt.)
1 Bale of cotton (India)	=	3.57145 cwt
1 Barrel of wheat flour (Canada, United States)	=	1 75001 cwt.
1 Bar, see Millier		
1 Bow (Java, Dutch Indies)	=	70.36998 square feet
1 Bushel (United States)	=	0 06896 bushels
1 Bushel of oats (United States)	=	32 lbs
1 Bushel of oats (Canada)	=	34 lbs
1 Bushel of wheat and potatoes (United States)	=	60 lbs
1 Bushel of barley (Canada, United States)	=	48 lbs.
1 Bushel of raw rice (United States)	=	45 lbs
1 Bushel of rye, hulled maize, linseed (Canada, United States)	=	56 lbs
1 Cadastral arpent (Hungary)	=	1 42201 acres
1 Cental (United States)	=	100 lbs
1 Centiare [10 square metres]	=	10 76392 square feet
1 Centigramme	=	0 15431 grains
1 Centilitre	=	0 0022 gallons
1 Centimetre	=	0 393715 inches
1 Centistere	=	0 35315 cubic feet
1 Centner (Germany, Austria, Denmark)	=	110.23171 lbs
1 Centner (Sweden)	=	93 71238 lbs.
1 Cho [60 ken] (Japan)	=	119 30327 yards
1 Cho (Japan)	=	2.45068 acres
1 Crown [100 heller] (Austria-Hungary)	=	10 d at par
1 Crown [100 öre] (Denmark, Norway, Sweden)	=	18 1 1/2 d at par
1 Cubic centimetre	=	0.06102 cubic inches
1 Cubic metre	=	1.30795 cubic yards
1 Decagramme [10 grammes]	=	0.35275 oz.

# LX WEIGHTS, MEASURES AND MONEY OF THE VARIOUS COUNTRIES

1 Decalitre [10 litres]	=	2.19976 gallons
1 Decametre [10 metres]	=	32.80840 feet
1 Decare [1000 square metres]	=	1195.98627 square yards
1 Decastere [10 cubic metres]	=	13.07951 cubic yards
1 Decliare [10 square metres]	=	11.95986 square yards
1 Deciatine [2 tchetwert] (Russia)	=	2.69966 acres
1 Decigramme	=	1.54323 grains

## CONTENTS

### ABSTRACTS

### AGRICULTURAL INTELLIGENCE.

#### I. — GENERAL INFORMATION.

DEVELOPMENT OF AGRICULTURE IN DIFFERENT COUNTRIES — 135. Agriculture in the State of São Paulo, Brazil, according to the President's Message to the Legislative Congress (Session of July 14, 1921).

RURAL HYGIENE — 136. The Part Played by the Rabbit and Other Domestic Animals in Protecting Man from Mosquitoes.

#### II. — CROPS AND CULTIVATION.

##### a) GENERAL.

AGRICULTURAL METEOROLOGY — 137. Effect of Lake Michigan (United States) upon Rain-fall during the Crop-Growing Season — 138. The Fertilising Value of Rain and Snow: Researches in Canada

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY — 139. Influence of Atmospheric Factors upon the Composition of Wheat — 140. Hard-Pan in the Apulian Soils and Its Origin. — 141. Research Made in Japan on Gases Formed in Rice Fields during the Decomposition of *Astragalus sinicus* used as a Green Manure. — 142. The Inversion of Saccharose by the Mineral Acidity of the Soil

METHODS OF CULTIVATION. — 143. The Prevention of Dust Storms in Canada.

MANURES AND MANURING. — 144. The World's Nitrogen Products. — 145. The Condition of the Nitrogenous and Phosphatic Fertiliser Industries in Germany — 146. Manurial Value of Tobacco Waste. — 147. United States Production of Fish Scrap and Meal — 148. The Sébakh of the "koms" or "Sébakh koufri", in Egypt.

INTERNAT. INST. OF AGRIC. *Internat Review of Science and Practice of Agriculture.*  
Year XIII, No. 2. Rome, February, 1922.

## b) SPECIAL.

- AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS. — 159. Distribution of Manganese in the Organism of Higher Plants. — 159. The Manganese Content of Seeds of Dutch Origin. — 151. Experiment to ascertain the Factors determining Resistance to Cooking in Leguminosae and on the Means employed to Remedy this Defect. — 152. A Contribution to the Determination of the Cause of the Formation of Bacteroids in the Nodules of Leguminosae.
- PLANT BREEDING. — 153. Instruction and Investigation in Plant Breeding at the College of Agriculture in the Philippines — 154. Genetic Behaviour of the Spelt Form in Crosses between *Triticum Spelta* and *Triticum sativum*. The Possibility of obtaining Synthetic Forms of Wheat by Crosses between Two Spelts. — 155. Variation and Correlation of Characters Among Rice Varieties Cultivated in the Philippines — 156. Leaf-Tissue Production and Water Content in a Mutant Race of *Phaseolus vulgaris* as compared with the Original Variety — 157. Production of Varieties of Bean with Mottled Seeds. — 158. Cotton Selection: Method Adopted in Egypt by the Sultanic Agricultural Society.
- CEREALS AND PULSE CROPS. — 159. Varietal Trials with Spring Wheat in North Dakota-U. S. Comparative Grain Yields and Milling and Baking Qualities — 160. The Composition of Wheat affected by Meteorological Conditions. — 161. Satisfactory Results obtained in Italy with a Variety of Rice from the United States — 162. Gembok Beans (*Bauhinia esculenta*) from South Africa.
- STARCH CROPS. — 163. Development of Potato Tubers. Experiments made in Colorado, U. S. A.
- FORAGE PLANTS, MEADOWS AND PASTURES. — 164. The Bargillo (*Mexhomia Rensoni*), a Good Leguminous Forage Plant, Indigenous in Central America — 165. "Florida beggar weed" (*Desmodium tortuosum*). — 166. Method for calculating the Production of Pastures.
- FIBRE CROPS. — 167. Piedmont Hemp. — 168. The *Agave* and *Fourcroya gigantea* at Tranninh, Indo-China. — 169. Giant Grasses for Paper-Making in India, Africa, Australia and the West Indies.
- PLANTS YIELDING, OILS, DYES, TANNINS, ETC. — 170. The Oil-Bearing Sunflower on the "Riviera di Ponente", Italy — 171. Gembok Beans (*Bauhinia esculenta*) as a Source of Oil. — 172. Mangrove Species Valuable as a Source of Tannin, in the Sunderbunds Forest Division of Bengal (India).
- RUBBER GUM AND RESIN PLANTS. — 173. Utilisation of Serum in the Dilution of Hevea Latex — 174. Observations on the Camphor Plant (*Blumea balsamifera*, D. C.) in Indo-China. — 175. Characters and Use of Cuica Resin Derived from *Cercidium spinosum*.
- STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL PLANTS. — 176. Notes on the Cultivation and Commercial Value of *Carica Papaya* in Ceylon and Future Possibilities in India: Investigations on the Composition of the Fruit.
- FRUIT GROWING — 177. Banana-Growing in Porto Rico.

## III. — LIVESTOCK AND BREEDING.

## a) GENERAL.

- HYGIENE — 178. The Effect of Chloropicrin Fumes on *Argus reflexus*. — 179. The Autopsy-therapeutic Treatment of Strangles — 180. Vaccination of Cattle against Anaplasmosis;

the Results of Inoculating High-Class Breeding Animals with Sheep and Goats' Blood Infected by Repeated Transmission. — 181. "Ghedda" or Hemorrhagic Septicemia of the Dromedary. — 182. Note on the Natural Spirillosis of the Rabbit (*Spirochaeta cuniculi*).

**FEEDS AND FEEDING.** — 183. A Calculation of the Amount of Food Necessary for Stock, Especially When Grazing, per 500 kg. of Live Weight — 184. Research on the Value of Different Processes for Disintegrating Straw. — 185. Researches Made in the United States on the Sodium Chloride Content of Stock Feeds. — 186. Gemshok Beans *Bauhinia esculenta* as Feeds for Cattle. — 187 The Change in the Fat of Peanut Fed Rabbits.

#### b) FEEDS AND FEEDING

**HORSES.** — 188 The Dongolao Horse. — 189 Depreciation in the Market Value of Broken-Kneed-Horses.

**CATTLE.** — 190. Comparative Feeding Value of Sunflower Silage and Darso Silage for Fattening Baby Beef during the Final Stage of Fattening. Experiments in the United States. — 191. Effect of Shelter and Temperature of the Drinking Water on the Increase in Weight of Fattening Cattle. Experiments in the United States

**PIGS.** — 192 The Gascon and Lauraguaise Breeds of Pigs in France — 193 Use of Forage Crops in the Fattening of Pigs Experiments in the United States.

**POULTRY.** — 194 First Egg Competition in France

**BEE-KEEPING.** — 195. Note on the South African Bee. — 196 Value of Formaline Vapour as Disinfectant in Apiculture, Especially in Combatting Foul Brood

**FISH BREEDING.** — 197. Fresh Water Pisciculture in North Africa — 198. Coccids of *Cottus gobio* and of Carp Fry.

### IV. — FARM ENGINEERING

**AGRICULTURAL MACHINERY AND IMPLEMENTS** — 199 Harvesting Sugar Cane by Machinery, and Advantages of the "Luce Sugar Cane Harvester" — 200 Apple Packing Houses in the North-Western Districts of the United States — 201 Tobacco Curing Barns and Packing Houses

### V. — AGRICULTURAL INDUSTRIES.

**INDUSTRIES DEPENDING ON ANIMAL PRODUCTS** — 202 The Practical Organisation of Milk Control in Belgium — 203 A Method for Detecting the Admixture of Goats' Milk to the Milk of Cows

### VI. — RURAL ECONOMICS.

**AGRICULTURAL PRODUCTS; PRESERVING, PACKING, TRANSPORT, TRADE** — 204 A Theoretical and Practical Study of the Ensilage of Forage Plants and of the Adaptation of the Process to the Requirements of Argentina — 205 Storage of Potatoes, Comparative Effects of Light and Darkness — 206. Transport of Market Produce by Aeroplane

## PLANT DISEASES.

### III. — DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

#### a) GENERAL.

**RESISTANT PLANTS.** — 207. Forms of Hop Resistant to Mildew (*Sphaerotheca Humuli* — 208. Red Currant Varieties Comparatively Resistant to American Gooseberry Mildew (*Sphaerotheca mors-uvae*) in England

MEANS OF CONTROL. — 209 The Efficacy of Fungicidal Dusts for the Control of Wheat Smut (*Tilletia Tritici*). — 210. Stem-Rust Infection in Wheat in North-Dakota, U. S. — 211. *Phyllosticta Montemartini* n. sp. a Deuteromycete Injurious to the Leguminales *Buddleia variabilis* in Italy. — 212. *Fusarium cubense*, a Hypomycete Injurious to the Banana in Porto Rico. — 213. *Colletotrichum Kaki* {n. sp., a Deuteromycete Injurious to *Diospyros Kaki* var *Kiombo*, in Italy. — 214. The Oak Oidium on the Chestnut Tree in Emilia, Italy.

## V. — INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

### a) GENERAL.

GENERAL. — 215. Artificial Production of "Tipburn" of Potatoes.

MEANS OF CONTROL — 216. *Howardula benigna*, n. gen. and n. sp., a Nematode Parasite of *Diabrotica vittata*, *S. trivittata* and *D. 12 punctata*, in the United States. — 217 *Oriolus luteolus*, A Bird Useful to Agriculture in India — 218 The Use of Crystalline Ferrocyanide of Potassium as an Insecticide. — 219 Experiments in the Control of the Olive-Fly (*Dacus Oleae*) by Means of the Lotrionte System of Traps ("capanette dachicide"), in Spain and Italy.

### b) SPECIAL.

INSECTS, ETC. INJURIOUS TO VARIOUS CROPS. — 220 The Potato-Tuber Moth (*Phthorimaea operculella*), in the Department of Herault — 221. *Crotoplastes* sp., a Scale-Insect Injurious to the Mate (*Ilex paraguariensis*), in the State of Paraná, Brazil — 222. *Lochmamea san, uniolenta*, a Coleopteron Injurious to the Melon in Catalonia, Spain. — 223. *Xylotodoris luteolus* a Rhynchote Injurious to the Palm *Oreodora regia* in Florida — 224 Insects Injurious to the Banana in Porto Rico

## EDITORIAL STAFF OF THE BUREAU OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES.

Chief of Bureau: Dr. JULES-MICHEL SAULNIER.

### Editors

Dr. GUIDO BORGHESE, Chief Rédacteur.  
Prof. GIULIO TRINCHIERI, Chief Rédacteur.  
Prof. GIROLAMO AZZI, Chief Rédacteur.  
THÉODORE BIÉLER, Lic. ès Sc. phys. et mat.,  
Chief Rédacteur.

Dr. FRANCESCA DORIO.  
FRÉDÉRIC SORG, Ing. Agr.  
MARGARITE L. YMO, Dipl. Hort. Sc.  
Oxford & Reading.

The Bureau assumes no responsibility with regard to the opinions and the results of experiments uttered in this Review.

The Editor's notes are marked (Ed.).

*In quoting articles, please mention this REVIEW.*

## CONTENTS

### FIRST PART: ORIGINAL ARTICLES

- JACOB ERIKSSON: The Mycoplasma Theory, Its Scientific Importance and Practical Significance . . . . . p. 269

### SECOND PART: ABSTRACTS.

## AGRICULTURAL INTELLIGENCE.

### I. — GENERAL INFORMATION

- AGRICULTURAL RESEARCH. — 226 The Present Position of Research in Agriculture in Great Britain and Suggestions as to the best Methods of Application to Practical Farming. — 227 Report of the "Imperial Economic Botanist" Pusa, India, 1920-1921 with reference to Wheat, Tobacco, Fibre Plants, Oil Seeds, Grain, and Indigo, including Physiological Investigations — 228 The New Service of Agricultural Ecology in Italy

### II. — CROPS AND CULTIVATION.

#### a) GENERAL.

- AGRICULTURAL METEOROLOGY — 229 Experimental Researches on the Critical Period of Wheat, as regards Rainfall in Italy
- SOIL PHYSICS AND CHEMISTRY — 230 Evaporation and other Soil Properties found to be connected with Soil Constitution — 231 The Chlorine Index as a Comparative Measure of the Nitrogen Content of Soils — 232 Researches on the Presence of Arsenic and Iodine in Soils and Subterranean Water in Argentina — 233 Concentration of the Hydrogen Ion in the Soil and in Plants — 234 Researches made in Denmark, upon the Effect of Soil Conditions on Bacterial Life and the Chemical Transportations taking place in the Soil: the Capacity for Decomposing Mannite.
- METHODS OF CULTIVATION. — 235 The Spring Awakening of Arable Land and the Choice of Agricultural Machines
- MANURES AND FERTILIZERS. — 236. The Conversion of Straw into Farmyard Manure — 237. Supplies of Organic Matter in the Soil; Research carried out at the Rothamsted Experimental Station. — 238. Physic Nut Cake as a Fertilizer. — 239. The Recent Conference at Rotterdam and the Future Prospects of Nitrate of Sodium.

#### b) SPECIAL.

- AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS. — 240. Studies relating to the Anatomy and Physiology of the Sugar-Cane in Cuba.

INTERNAT. INST. OF AGRIC. *Internat. Review of Science and Practice of Agriculture.*  
Year XIII, No. 3. Rome, March, 1922.

- PLANT BREEDING.** — 241. Notes on the Work of the Phytotechnical Station at Gayerovo (Paraná), Brazil. — 242. Hereditary Behaviour of a Dwarf Form of Barley in Japan. — 243. Svalöfs Odal, a New, Early Variety of White Oats suited to North Sweden. — 244. The Inheritance of the Character « Yellow Striping » in the Oat. — 245. Inheritance of the Character, Crinkly Leaf, in Maize. — 246. A Septorial Chimera obtained, by Crossing two Varieties of Maize in India. — 247. A Case of Dimorphism in Rice connected with Segregation Phenomena. — 248. On the Fixity of Characters in New Hybrid Potatoes. — 249. Pure Line Selection of the Bundelkhand Cottons in India. — 250. Male-Sterility in Flax, Subject to two Types of Segregation, Ambilateral and Unilateral. — 251. Contribution to the Study of Bud Variations of Economic Importance in the Sugar Cane. — 252. Breeding Experiments with Roselle, *Hibiscus Sabdariffa*, in India.
- SEEDS.** — 253. The Possibility of Determining the Value of Seed by Biochemical Means
- CEREALS AND PULSE CROPS.** — 254. Varieties of Wheat cultivated in the Province of Cagliari, Sardinia. — 255. Experiments with Wheat Varieties in India. — 256. Mausholt III, a Variety of Oats Resistant to Lodging. — 257. The World Production of Soya.
- FORAGE CROPS.** — 258. Forage Production in Southern France and North Africa. — 259. A New Forage Grass from Uganda, *Pennisetum polystachyum*. — 260. Cultivation of Lucerne in the Monsoon Districts in India. — 261. Alfalfa Production under Irrigation, Experiments in the United States and in New South Wales. — 262. The Chemical Composition of Mangolds, Analyses Made in New South Wales
- FIBRE CROPS.** — 263. The Decline in the Yield of Egyptian Cotton and its Causes. — 264. Cultivation Trials of « patwa » (*Hibiscus cannabinus*) in India.
- PLANTS YIELDING OILS, ETC.** — 265. The Cultivation and Production of the Olive Tree in Spain. — 266. Illipe Nuts of British North Borneo from *Shorea stenoptera* and other Dipterocarps. — 267. The Value of the Oil of the Physic or Purging Nut (*Jatropha curcas*) and Utilisation of the Residual Cake as Manure. — 268. Economic Value of the Seeds of *Carthamus* spp. and their Oil Product.
- DYES.** — 269. Observations on the Cultivation of Java Indigo at Pusa, India
- SUGAR CROPS.** — 270. The Qualities of Java Seedling Sugar Canes and suggested Introduction into Louisiana, U. S. A. — 271. Tests of New Methods of Propagating the Sugar-Cane in Cuba.

### III. — LIVESTOCK AND BREEDING.

#### a) GENERAL.

- HYGIENE.** — 272. *Helenium hoopesii*, a Poisonous Plant, harmful to Stock in Utah, U. S. — 273. Use of Stomoxines in the Treatment of Infectious Diseases of Live Stock. — 274. Protozoon Parasites of Domestic Animals in Transcaucasia. — 275. Researches on the Mite -- Destroying Power of some Substances used as Remedies for Parasites Mange in Horses. — 276. A New Disease of Oxen: Contagious Acute Encephalitis. — 277. Vaccination of Cattle against Rinderpest. — 278. Summary of Experiments on Foot-and-Mouth Disease in France. — 279. Intestinal Coccidiosis of the Pig.
- FEEDS AND FEEDING.** — 280. Experimental Studies on the Systematic Use of Food for Cattle in the United States. — 281. Hay Made from liberally Fertilised Young Grass, a Farm Grown Concentrated Food. — 282. Connection between Degree of Milling and the Composition and Food Value of Bran.
- BREEDING.** — 283. Colour Inheritance in Mammals and Domestic Birds. — 284. Mutations observed in the Skunk (*Mephitis pudica* and *M. hudsonica*) in the United States. — 285. Measurement of the Cutaneous Surface of the Horse. — 286. Characters of the Chilian Horse. — 287. The Donkey of Catalonia, Spain.

### III. — LIVESTOCK AND BREEDING.

#### a) GENERAL.

- CATTLE.** — 288. The Cattle Industry of Cuba. — 289. Improvement of Dairy Cattle by Milk Control in Denmark. — 290. The Utilisation for Grazing-Grounds of the De-forested Lands in the South of the United States. — 291. The Value of Beet Molasses in the Ration for Fattening Steers. — 292. The Sterilisation of Cows — 293. Possibility of increasing the Milk Yield in the Charlorais race.
- SHEEP.** — 294. Sheep-Rearing on Temporary Pastures in the United States. — 295. Experiments in Rearing Sheep and Goats in the United States.
- PIGS.** — 296. Sorghum as a Pig Food
- SERICULTURE.** — 297. Suggestions with a View to the better Notation of the Shape of the Silkworm Cocoon and of its Variations. — 298. Simple Method of obtaining several Generations of Silkworms in one Year — 299. Experiments in Silkworm Crossing with Bivoltine Males in Italy. — 300. Connection between the Time of gathering Mulberry Leaves and the Silk Yield of *Bombyx mori*
- VARIOUS ANIMALS.** — 301. The Italian Sheep-Dog — 302. Breeding Fur-Bearing Animals in Canada in 1920. — 303. Horse Chestnuts as a Food for Rabbits

### IV. — AGRICULTURAL MACHINERY.

304. Condition of Motor-Cultivation in Germany — 305. American and German Agricultural Machines — 306. The Construction and Use of Agricultural Tractors in Italy. — 307. EULM Tractors for Ploughing and other Agricultural Work. — 308. "AGRO" Fore-Carriage Tractor. — 309. Power of the Engines of Tractors. — 310. Wedging a Tractor — 311. Rear-driven Tractors — 312. A Charcoal Gas-Engine for Tractors. — 313. Accidents due to Tractors. — 314. The "Buckeye" Tractor Ditcher for Land Drainage. Trials in England — 315. Motor-Plough for Ploughing on the Flat — 316. New Machine with Flexible Teeth and Rotating Forks — 317. Choice of Agricultural Machines on Arable Land. — 318. PANTZIER antzler Machine for Chopping and Distributing Manure — 319. Decortication of Beet Seed — 320. HAUPT Potato-Planter with Cylindrical Hopper — 321. Motor Mowers. — 322. Reaper-Binder for Tractor — 323. Stooker for large Threshing-Machine. — 324. The LASKOWSKI Apparatus for Preventing Accidents during Threshing. — 325. Carrying the Harvest on a Light Road Tractor. — 326. The GUIDETTI and PIAZZA Cellar Presses — 327. On the Choice of a Pump — 328. A Deep Suction Pump — 329. The Work of Teams — 330. Dynamometers.

### V. — AGRICULTURAL INDUSTRIES.

- STORAGE OF CROPS.** — 331. Investigations on Potato Storage during the Hot Season in Western India. — 332. Changes occurring in Oranges in the Course of Preservation — 333. Causes of Inferiority of Manila Hemp Fibres (*Musa Textilis*) in recent Consignments.

### PLANT DISEASES.

#### II. — DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

334. Heat-rot or Black-heart in Potatoes in India — 335. Further Researches on the Dry Gummosis of Citrus Trees.

### III. — DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

#### a) GENERAL.

RESISTANT PLANTS — 336. "Excelsior" Oats Resistant to Rust in Brazil. — 337. Hybrid Potatoes Resistant to Mildew (*Phytophthora infestans*) in France — 338. Behaviour of different Varieties of Sugar Cane towards Diseases and Pests. — 339. Types of Sugar-Cane native to Java, Resistant to Disease and to the Cane-Borer (*Diatraea saccharalis*).

#### b) SPECIAL.

DISEASES OF VARIOUS CROPS — 340. Types of North American Oats attacked by Rust, in Brazil — 341 "Ring Disease" (*Bacillus Solanacearum*) and Dry Rot (*Fusarium* sp.) of the Potato, in India. — 342 Observations on *Dothidella Ulei*, an Ascomycete Injurious to *Hevea Brasiliensis* in South America. — 343. *Vermicularia Capsici* a Deuteromycete Injurious to *Capsicum annum* and *C. frutescens*, in Bihar, India — 344 *Phyllosticta Congesta*, a Deuteromycete Injurious to *Prunus triflora* in Georgia

### V. — INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

#### a) GENERAL.

GENERAL — 345. Coccidae from the Seychelles. — 346 A Revision of the Genus *Locusta* L. (*Pachytylus* Fieb.) with a New Theory as to the Periodicity and Migrations of Locusts

MEANS OF CONTROL — 347 *Isaria Eristalisidis*, a Hyphomycete living on the Dipteran, *Eristalis tenax*, in Japan — 348 New Species of Indian Braconidae — 349 Control Measures against the "Pink Boll-Worm" (*Golechia Gossypiella*) of the Cotton Plant, in Egypt — 350 Control of Olive Fly (*Dacus oleae*) during 1920 in Greece.

#### b) SPECIAL.

INSECTS INJURIOUS TO VARIOUS CROPS. — 351 "Potato Moth" (*Phthorimaea operculella*) in Tunisia — 352 "Potato Moth" (*Phthorimaea operculella*) in India. — 353 *Neorotoma nemoralis*, a Hymenopteron Injurious to the Peach-tree, in France — 354 The Coccid, *Chrysomphalus auranti*, in the Colony of Kenya, East Africa. — 355 *Rhagoletis suavis*, a Dipteran Injurious to *Juglans* spp. in the United States — 356 *Chloritya lybica*, n. sp. a Rhyncote Injurious to the Vine in Libia. — 357. New Species of Curculionidae attacking Forest Trees in India — 358 The Tussock Moth (*Lymantria monacha*, in Valais, Switzerland. — 359 *Platypus omnivorus*, a Beetle Injurious to Wood, in New South Wales.

*In quoting articles, please mention this REVIEW.*

## CONTENTS

### ABSTRACTS.

### AGRICULTURAL INTELLIGENCE.

#### I. — GENERAL INFORMATION.

- DEVELOPMENT OF AGRICULTURE IN DIFFERENT COUNTRIES. — 360. The Present Position of Agriculture in the Philippine Islands. — 361. Agriculture in Corfu.
- RURAL HYGIENE. -- 362. Fleas and the Methods of their Control. — 363. Lathyrism. — 364. Flora of Maize Flour.
- AGRICULTURAL EXPERIMENTATION. — 365. Suggestions for the Organisation of Stations for Agricultural Research in France and the French Colonies. — 366. Agricultural Experiment Stations in Czecho-Slovakia. — 367. The Standardisation of Field Experiments. — 368. Experimentation and Yield of Cotton, Sugar Cane, Bay Trees, and other Crops in Montserrat, West Indies. — 369. The Establishment of the West Indian Agricultural College in Trinidad.

#### II. — CROPS AND CULTIVATION.

##### a) GENERAL.

- AGRICULTURAL METEOROLOGY -- 370. Studies on the Reduced Yield of the Chief Farm Crops, especially as caused by Adverse Weather Conditions in the United States — 371. The Control of the Effects of Wind by Means of Plant Wind-Breaks in Tropical America. — 372. Effect of the Length of Day on the Differentiation of Characters of certain Lucerne Varieties and the Possibility of Utilising this Phenomenon as a Practical Means of Identification — 373. Influence of Light and Temperature on Sexual Expression in Hemp. — 374. On average Soil Temperature. — 375. Soil Temperature and its Effects on the Development of the Nodules of Leguminosae. — 376. Preparation of Soil Solution. — 377. Connection between the Hydrogen-ion concentration of Soils and their Need of Lime. — 378. Stratification and Hydrogen-ion Concentration of the Soil in Relation to Leaching and Plant Succession with special Reference to Woodlands — 379. The Carbon Coefficient for Determining the Organic Matter in Soil. — 380. Studies on *Clostridium Pastorianum* as a Fixer of Nitrogen.

INTERNAT. INST. OF AGRIC. *Internat. Review of Science and Practice of Agriculture.*  
Year XIII, No. 4. Rome, April, 1922.

**HYDRAULICS AND PERMANENT IMPROVEMENT.** — 381 Irrigation Schemes in the Niger territory of the French Soudan. — 382. The Improvement of Arable Land and Meadows in Czecho-Slovakia.

**MANURES AND MANURING.** — 383. Further Experiments with Activated Sludge in England. — 384. Experiments with « Rhenania Phosphat » in Germany. — 385. Results of Two Years Experiments with Superphosphate, "Tetraphosphate" and Phosphorite in Italy. — 386. Studies on Sulphur as a Factor in Soil Fertility.

b) SPECIAL.

**AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS.** — 387 Differentiation of Character in young Lucerne in Relation to Length of Daylight. — 388. Sexual Expression in Hemp in Relation to Light and Temperature — 389 Chemical Composition of Maize Cobs at different Stages of Maturity. — 390 Occurrence of Quercetin in a Type of Brown-Husked Maize. — 391. Composition of Wild Beets. — 392 Formation of Alcaloids in Belladonna Leaves, in Relation to Solar Radiation. — 393. The Influence of Light and of Fluctuating Temperatures on the Germination of *Poa compressa* — 394. Effect of Soil Temperature upon the Development of Nodules on the Roots of certain Leguminosae.

**PLANT BREEDING** — 395 Observations on Heredity made at the Phytotechnical Station at Abed (Denmark). — 396 The Establishment of a new Vine selection Station in Austria. — 397 Experiments in Selection and Hybridisation made with the Object of obtaining Types of Oats for Norrland (North Sweden). — 398 Researches on the Question of a Fatuoid Mutation of *Avena Sativa*. — 399 Rice Selection in the Philippine. — 400 Behaviour of the Hybrids *Medicago sativa* × *M. falcata* from the Standpoint of the Production of Types of Lucerne suitable for Central Sweden. — 401. On the Origin of a new Line of Red Clover with short Corolla Tube — 402. Experiments on the Fertilisation of Red Clover (*Trifolium pratense*) in Germany — 403. Genetic Behaviour of a new Seed Colour in *Trifolium pratense*. in Sweden — 404. The Histological Characters of the Root of the Sugar Beet from the Point of View of Selection

**SEEDS.** — 405. A Bio-Chemical Index for determining the Vitality of Seeds. — 406 The Exportation of Red Clover Seed from Czecho-Slovakia — 407. Steady Decline in Price of Vegetable Seeds in the United States since 1918

**CEREALS AND PULSE CROPS** — 408. Reliability of the Nail Test for predicting the Chemical Composition of Sweet Maize. — 409. Rice in the Philippines — 410. Rice-Growing in Messenia, Greece — 411 The Amount of Phosphatic Fertiliser necessary for Rice. — 412. Additional notes on Adlay (*Coix Lacryma-Jobi* var. *mayuen*), in the Philippines. — 413 Alimentary Value of Some Indo-Chinese Leguminosae.

**FORAGE CROPS.** — 414. The new Chinese Variety of Lucerne in South Africa. — 415. Experimental Trials in Natal with "Huban" Clover, a new Variety of *Melilotus alba* var. *annua*.

**FIBRE CROPS.** — 416 Cotton Growing in Algeria. — 417 [Irrigation Schemes in the Niger Territory of the French Sudan and the Extension and Improvement of Cotton Production. — 418. Cotton Growing in Queensland. — 419. New Fibre Crops in the Belgian Congo, and their Industrial Value. — 420. The Possibilities of developing the Roselle (*Hibiscus Sabdariffa* var. *altissima*) Fibre Industry in the Federated Malay States.

**RUBBER GUM AND RESIN PLANTS.** — 421. The Quality of the Rubber of *Hevea brasiliensis*; its Variations and their Causes; Economic Importance for the Amazon Rubber Industry. — 422. Investigations made in Java concerning the Origin of the Latex of *Hevea brasiliensis*.

**SUGAR CROPS.** — 423. Sugar Beet Cultivation in Louisiana, United States. — 424. Wild Beets: Composition and Value

- STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL PLANTS.** — 425. The Possibility of Growing Tea in Italy. — 426. Manuring Coffee. — 427. The Cocoa Industry of Ecuador and Possibilities of introducing certain Varieties into Other Countries. — 428. Factors other than those of Environment influencing the Quantity of Alkaloids contained in, and the Yield of Latex from the Opium Poppy in India. — 429. Influence of Solar Radiation Culture of Belladonna and on the Formation of Alkaloids in the Leaves.
- PLANTS YIELDING OILS, DYES, TANNINS, ETC.** — 430. Interplanting of Trees on Coconut Estates. Observations made in Portuguese India. — 431. The Cultivation and Commercial Possibilities of Safflower Seed (*Carthamus tinctorius* L.) in India.
- HORTICULTURE.** — 432. The Cultivation of Capsicums in Algeria. — 433. Possibilities of Mushroom Industry in India.
- FRUIT GROWING.** — 434. The Avocados of Guatemala. — 435. Propagation of Date Palms by Seed. — 436. Fruit Trees that can be Interplanted on Coconut Estates
- VINE GROWING.** — 437. Viticultural Questions in Italy. — 438. Substituting Shield Grafting for Double Cleft Grafting in Vines.
- FORESTRY.** — 439 Forestry in Norway and the Official Efforts for its Advancement. — 440 Effect of Orientation upon the Success of the Transplantation of Forest Trees. — 441 Paraguay Timber Industry. — 442 The Timber of India and Burma. — 443. Determination of the Value and Uses of the Various Timber and other Forest Products in British North-Borneo

### III. — LIVESTOCK AND BREEDING.

#### a) GENERAL

- HYGIENE.** — 444. Studies on Foot-and-Mouth Disease in France — 445 *Solenoptes capillatus*, a Sucking Louse in Cattle, hitherto unknown in the United States. — 446 Diseases and Parasites of Sheep in Syria — 447. Stomoxes as Carriers of Dromedary Trypanosomiasis
- ANATOMY AND PHYSIOLOGY** — 448 Experimental Researches on the Effects of Castration. — 449. The Possibility of Castrating Animals by the Use of Serums. — 450. The Rejuvenescence of Animals ; Experiments on old Fowls and Doe-Rabbits

#### b) SPECIAL

- HORSES.** — 451. Horse Breeding in Czecho-Slovakia. — 452. Study on Horse-Breeding in the United States. — 453. Essays on the Depreciation in the Selling Value of Injured Horses. Permanent Lameness — 454. LESBOUYRIES Pincers for Castrating Horses.
- CATTLE.** — 455. New Methods of Judging Cattle. — 456. Wintering and Summer Fattening of Cattle in North Carolina, United States
- SHEEP.** — 457. Sheep Breeding in Syria and Cilicia — 458. Fertility in Shropshire Sheep in the United States. — 459. Lamb-Fattening Experiments in the United States
- PIGS.** — 460. Swine-Feeding Experiments in Kansas, United States. — 461. Concentrated Pig Foods. Experiments made in France.

- BEEKEEPING.** — 462. Apiculture in Cuba and the Purity of Cuban Honey. — 463. Treatment of "Acarine Disease" (Isle of Wight Disease), of Bees.
- SERICULTURE.** — 464. The Present Condition of Sericulture in Syria. — 465. Observations and Researches on the Causes of the Persistence and Diffusion of Pebrine in Italy, notwithstanding the Selection of the Silk-Worm Eggs. — 466. The Use of Low Temperatures to destroy *Bombyx* Chrysalids.

#### IV. — FARM ENGINEERING.

- AGRICULTURAL MACHINERY AND IMPLEMENTS.** — 467. Tractor or Motor-Plough? — 468. One-Wheel Tractor l'HERMITE System. — 469. "Massimo" Tractor for Ploughing on Slopes. — 470. The Heavy-Oil Engine for Agricultural Purposes. — 471. Means of Attachment for Tractors to Farm Vehicles. — 472. Windlass for Cable Ploughing which automatically Changes its Position in Two Directions. — 473. Plough for the Rudolf SACK Tractor. — 474. Notes on Implements for Motor-Ploughing. — 475. Method of Fixing Mould-Boards on Ploughs: Deutsche Last-Automobilfabric System. — 476. RICHTER Hoe for Potato Ridging. — 477. Working the Soil with a Disk-Harrow. — 478. RENNIGER's Apparatus for Cleaning Seeds — 479. BREITE Potato Sorter. — 480. CARLSON Straw-Press combined with Thresher — 481. Automatic Distributor of Oats for Horses, MIEHE System — 482. Double Stroke Wind Engine. — 483. A Chest of the FUNKE Type, to be used in Testing Milk. — 484. A Mercury Vapour Current Transformer for use in the Country.

#### V. — RURAL ECONOMICS.

485. Farm Organisation in Bohemia. — 486. Evaluation of the Risk in Agricultural Enterprises and Assurance of Crops against Adverse Weather Conditions in the United States of America — 487. Cost of Rice Production in the Philippines. — 488. Notes on Coffee Growing in Brazil. — 489. Cost of Colt Breeding up to three Years in the United States. — 490. Cost of Milk Production in some of the States of North America

#### VI. — AGRICULTURAL INDUSTRIES.

- INDUSTRIES DEPENDING UPON VEGETABLE PRODUCTS** — 491. Modern Processes of Wine-Making Technique. — 492. Experiments in Fermenting Kaki Fruits. — 493. The Raw Materials used in the Italian Alcohol Industry. — 494. Experimentation in Milling and Baking of "Adlay" Grain (*Corn Lacryma-Jobi var. mayuen*). — 495. Oil from the Pips of French Grapes. — 496. The Utilisation of the Residues of Oil Extraction from Olives. — 497. Economic Value of Sunflower Oil: Tests made in Great Britain.
- INDUSTRIES DEPENDING UPON ANIMAL PRODUCTS.** — 498. Variations in the Percentage of Fat in Successive Samples of Cows Milk. — 499. Brown Glass Milk Bottles and their Use in Preventing Milk acquiring abnormal Flavours and Odours due to the Action of Light. — 500. Influence of Foreign Matter upon the Number of Bacteria in Milk. — 501. Type of Lactic Acid produced by Starters and by the Organism isolated from them. — 502. Connection between the Number of the Bacteria in the Milk and the Quality of the Cheese obtained.
- AGRICULTURAL PRODUCTS, PRESERVING, PACKING, TRANSPORT, TRADE.** — 503. Chemico-Bacteriological Study of Different Qualities of Silaged Forages.

## PLANT DISEASES.

## I. — GENERAL.

LEGISLATION AND ADMINISTRATION FOR PLANT PROTECTION — 504. Government Enactments in Formosa regulating the Importation and Exportation of Plants — 505. Decree of April 7, 1922, No. 148, Respecting the Control of *Chrysophlyctis endobiotica* in Czecho-Slovakia. — 506. Decree of October 25, 1921, Respecting Insectivorous Birds and Bird-Catching in Belgium. — 507. Law No. 20 of July 20, 1921, relating to the Control of the Pink Boll Weevil and of the Seed of the Cotton Plant, in Egypt — 508. Plant Quarantine Service in the Philippines

## II.— DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN

509. Sulphate of Iron and Perchloride of Iron in the Treatment of Chlorosis of the Vine

## III. — DISEASES DUE TO FUNGI

## BACTERIA AND OTHER LOWER PLANTS.

GENERAL — 510. Reduced Yield of chief Crops, due to Fungoid Diseases, Insects and Animal Pests in the United States of America — 511. Insufficient Phosphatic Fertiliser a Factor favourable to the Development of Rice Diseases

RESISTANT PLANTS — 512. Varieties of Potatoes resistant to *Synchytrium Solani* in Great Britain — 513. Type of Cotton Plant cultivated in Montserrat, resistant to Disease and seldom attacked by "Cotton-Stainers" (*Dysdercus* and *Oncocnemis* spp.) — 514. Resistance of Venezuela Cocoa Varieties against Attack of *Monilia*, in the Republic of Ecuador. — 515. *Botrytis antheranum Trifolii*, Fungus injurious to the *Trifolium pratense* in Germany,

DISEASES OF VARIOUS PLANTS. — 516. *Fusarium* sp. a Deuteromycete the probable Cause of Disease of the Leguminosae, *Crotalaria juncea* and *C. usaramocensis*, in Tonkin — 517. *Colletotrichum Gossypii* and *Cercospora Batatae*, Deuteromycetes new to the Philippines and Injurious to the Cotton Plant and the Sweet Potato respectively — 518. *Cercospora Arachidis* var. *macrospora* n. var., a Hyphomycete injurious to the Peanut in Lombardy, Italy. — 519. The Mucoraceae, *Rhizopus nigricans*, Injurious to Pumpkins, in Italy — 520. *Penicillium crustaceum*, the Cause of Rot in Quinces, in Italy

## IV. — WEEDS AND PARASITIC FLOWERING PLANTS.

521. *Striga densiflora* and *Scrophularioides* Scrophulariaceae Parasitic on the Sugar-Cane in India.

## V. — INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

## a) GENERAL.

GENERAL. — 522. On the Etiology of the Potato Disease known as Tip-burn in the United States. — 523. Observations made on the Life-History of *Laspeyresia pomonella* in the Valley of the Grand Colorado. — 524. Propagation of Date Palms by Cuttings favouring the Development of *Phoenicococcus marlatti*

RESISTANT PLANTS. — 525. Resistance of *Coix Lacryma-Jobi* var. *mayuen* to Animal Pests in the Philippines.

MEANS OF CONTROL. — 526. *Tricholeps tantulus*, a Natural Rhynchote Enemy of the Pink Cotton Boll Weevil (*Platyedra gossypiella*), in India. — 527. *Terpsiphone paradisi*, a Bird useful to Agriculture in India.

## b) SPECIAL.

- INSECTS ETC INJURIOUS TO VARIOUS CROPS — 528 Insect Enemies of Rice in the Philippines —  
 529 *Leptocorisa acuta*, a Rhynchote injurious to Rice in the Philippines — 530 *Dysdercus* sp Rhynchote injurious to *Hibiscus Sabdariffa* var *alissima* in the Federated Malay States — 531 *Laphygma exempta*, a Macrolepidopteron injurious to Sugar Cane and Maize new to Queensland — 532 *Cerococcus parahybensis*, a Scale-Insect found on the Coffee Plant, in the State of Parahyba, Brazil — 533 *Ypsolophus marginellus*, a Microlepidopteron injurious to the Juniper, New Jersey, United States

# EDITORIAL STAFF OF THE BUREAU OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

Chief of Bureau. Dr JULES-MICHEL SAULNIER

## Editors

Dr GUIDO BORGHESEANI, Chief Rédacteur  
 Prof GIULIO TRINCHIERI, Chief Rédacteur.  
 Prof GIROLAMO AZZI, Chief Rédacteur.  
 THÉODORE BIÉLER, Lic ès Sc phys et mat.,  
 Chief Rédacteur

PAUL CASTELLAN Ing. Agr.  
 Dr. FRANCESCA DORIO.  
 MARGARITE L. YEO, Dipl. Hort. Sc.  
 Oxford & Reading.

The Bureau assumes no responsibility with regard to the opinions and the results of experiments outlined in this Review.

The Editor's notes are marked (Ed.)

*In quoting articles, please mention this REVIEW.*

## CONTENTS

### FIRST PART: ORIGINAL ARTICLES.

- M. MAT. — Improvement in Administrative Methods in the Belgian Ministry of Agriculture Brussels . . . . . Page 616

### SECOND PART: ABSTRACTS

## AGRICULTURAL INTELLIGENCE.

### I. — GENERAL INFORMATION.

- AGRICULTURAL INSTRUCTION — 534 Opening of an Autumn School for Shepherds at Rambouillet, France
- AGRICULTURAL AND FORESTRY RESEARCH AND CONTROL — 535 The Botanical Research Station in Denmark. 536. — The Forest-Research Stations in Denmark, 537. — Two Cider-making Stations: The Fermentation Laboratory and Central Cider Brewery at Ettelbruck (Grand Duchy of Luxemburg). — 538. Accuracy in Experiments carried out at the Danish State Experiment Stations with Varieties and Strains of Roots.

### II. — CROPS AND CULTIVATION.

#### a) GENERAL

- AGRICULTURAL METEOROLOGY. — 539. Influence of Temperature and Rains on the Maize Yield in Argentina. — 540. Influence of Rain on the Hay-Crop of certain Forage-grasses at Svalöf, Sweden. — 541 Present Phase of Protection against Frost by means of Fumigation in the "Grand Valley" of Colorado
- SOIL PHYSICS AND CHEMISTRY — 542 Clay as an Ampholyte. — 543. Partial Sterilisation of the Soil by means of Arseniate of Soda
- MANURES AND MANURING. — 544. Fertilisers in Spanish Agriculture. — 545. Inoculated Leguminous Plants as Nitrogenous Fertilisers. — 546. Tobacco Refuse as a Fertiliser. — 547. Experiments with Potash Fertilisers in the United States. — 548. Experiments on the probable Effect produced by the Addition of Sulphur to the Soil.

INTERNAT. INST. OF AGRIC. *Internat. Review of Science and Practice of Agriculture.*  
Year XIII, No. 5-6 · Rome, May-June, 1922.

## b) SPECIAL.

- AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS.** — 549. Distribution of Manganese in the Organism of the Higher Plants. — 550. Chemical Composition of Diss Ergot and Oat Ergot. — 551. Methods of Colloidal Chemistry in Plant Physiology. Sensitiveness of Lupins to Alkaline Earth Metals. — 552. Influence of Mechanical Pressure on the Growth and Structure of Wood. — 553. The Multiplicity of the Species of Radicular Bacteria in Plants observed by means of serological Processes.
- PLANT BREEDING.** — 554. Improvement of the "Civitella" Variety of Wheat by Individual Selection in Tuscany. — 555. "Rubin", an early Spring Wheat for Central Sweden obtained by Crossing the Native Dala Variety with Kolben of Svalöf. — 556. Orion of Svalöf, an early black Variety of Oat for the Norrland obtained by the Cross Ligowo 0668. — 557. An Enumeration of the dominant Characters of Barley. — 558. Behaviour of the Character "Ramified Female Inflorescence" in the Cross with Maize. Plants having normal Ears. — 559. The Improvement of the Oil-Bearing Sunflower by Selection, in Bulgaria. — 560. On the Advisability of Selecting the Native Tobaccos in Bulgaria. — 561. Difficulties arising in Experiments on the Improvement of Fruit-Trees by means of Crossing and Selection. — 562. The Possibility of Transmitting by Vegetative Propagation the Character of High Productivity in certain Apple-Trees. — 563. Means of obtaining by suitable Crossing, Varieties of Grapes without Pips.
- CEREALS AND LEGUMINOUS SEEDS.** — 564. A Monograph on the Wheat Plant. — 565. The chief causes of the low Yields of Maize in South Africa and possible Means of Improvement — 566. An Experiment with *Sorghum vulgare* from the Bombay Presidency, in Singapore.
- FORAGE CROPS, MEADOWS AND PASTURES.** — 567. Sugar Sorghum, a good rust-resistant Feed. — 568. Star Grass (*Cynodon plectostachyum*), a valuable Fodder Grass in South Africa — 569. Cultivation and Forage Value of the Velvet Bean (*Stizolobium deerin-gianum*) in Rhodesia.
- FIBRE CROPS.** — 570. A new Flax Seed in Ireland giving an exceptionally high Yield of good Quality Fibre. — 571. Note on the Culture of the Cotton Plant in Tunisia. — 572. Cotton Ratooning Experiments in South Africa.
- PLANTS YIELDING OILS, DYES, TANNINS, ETC.** — 573. Cultivation of Coconut Palms and Production of Copra in Dahomey, French West Africa. — 574. The Tannin Content of some South Indian Wattles (*Acacia* spp.).
- RUBBER, GUM AND RESIN PLANTS.** — 575. On the Influence of Tar on Hevea Bark.
- STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL PLANTS.** — 576. Cacao Cultivation in Grenada. — 577. Cinnamon: Sources, Production and Trade. — 578. Effects of *Cucurbita Pepo* Seeds on Kidney Excretion.
- HORTICULTURE.** — 579. The Utilisation of Paper Mulch in Pine Apple and Sugar Cane Cultivation in Hawaii. — 580. The Cultivation of Blueberries (Whortleberries) (*Vaccinium* spp.) in the United States. — 581. Cultivation of the Loganberry in France. — 582. Gramineae and other Lawn Plants Resistant to Drought. — 583. Flower Bulbs on the French Riviera.
- FRUIT GROWING.** — 584. The Cultivation of the Date Palm in Mesopotamia and Investigations as to the Yield.
- VINE GROWING.** — 585. Factors influencing the Increase in Grape Yield in Western India. — 586. Grape Preservation in Almeria: Cultivation and Preservation Experiments made in Italy.

**FORESTRY.** — 587. Forestry Journal, Forestry, Timber-Trade and Wood-Working Industries Journal and Serials. — 588. Forestry in the Straits Settlements. — 589. Experiments in the Preservation of Acorns and Beech-Mast in Denmark.

### III. — LIVESTOCK AND BREEDING.

#### a) GENERAL.

- HYGIENE.** — 590. Plants Poisonous to Live-Stock. — 591. Is the Sorrel Dock (*Rumex Acetosa*) Poisonous to Cattle? — 592. Observations on the Treatment of Puerperal Infection in Domestic Animals by Treatment with Iodide of Ioduretted Potassium. — 593. Notes on Contagious Abortion in Female Asses and Mares. — 594. Horse Pest. — 595. New Endoscopic Methods for the Examination of the Horse. — 596. The Simultaneous Method of Inoculation with Anti-Rinder Pest Serum. — 597. On an acute and epidemic Form of Parenchymatous Hepatic Inflammation in Sheep
- FEEDING.** — 598. The Use of Calcium Salts in the Feeding of Animals. — 599. Boiled Cotton Seeds as a Stock Feed.
- STOCK BREEDING.** — 600. Variability in Domestic Animals and the Value of Statistics in Researches connected with Stock Breeding Part II. — 601. The Mating of nearly-related Cattle
- STOCK RAISING.** — 602. Bill for the Improvement of Agricultural Live Stock in England — 603. Thirty Years Experimental Stock Breeding in Utah.

#### b) SPECIAL

- HORSES.** — 604. Breeding Morgan Thorough-Breds on Government Farms in the United States. — 605. Trade in Irish Horses
- CATTLE.** — 606. Frisian Cattle. — 607. The dual Purpose Shorthorn Breed — 608. Comparative Study of Maize Silage and Sorghum Silage for Fattening Cattle. — 609. Silaged Forages for Milch Cows, in Great Britain. — 610. Studies made at the Maine Agricultural Station (United States), on the Lactic Secretion of different Breeds of Cattle. — 611. The Period of Lactation as a Factor in the Variation of the Percentage of Fat in Cow's Milk — 612. Butter Production Records for the different Breeds of Milch Cows in Kansas
- SHEEP.** — 613. The Herdwick Sheep, a good Breed for poor Mountain Lands. — 614. Intensive Feeding of Ewes at Lambing Time and other Means of increasing the Production of Lambs.
- PIGS.** — 615. The Improved German Pig as a Means of improving Swine in the Province of Gorizia, Italy. — 616. The Influence of Age upon the Fertility of Sows. — 617. Oats as a Pig Feed.
- POULTRY.** — 618. Four new Breeds of Fowls. — 619. The Croad Langshan Breed of Fowl. — 620. The Treatment of contagious Entero-Hepatitis in Turkeys with Ipecacuanha. — 621. Inheritance of silky Plumage in Fowls. Historic Account and Description of the Sporadic Appearance of Individuals with silky Plumage among normal Birds and their genetic Relation. — 622. The respective Influences of Cock and Hen in Egg Production. — 623. The Dryden Method of choosing laying Hens. — 624. The Duck as an Egg-Layer.

**BEEKEEPING.** — 625. Bee-Keeping in Rhodesia. — 626. Experimental Centre in the Shetland Isles for rearing the Pure-Bred, Black, Scottish Bee. — 627. The Melilots as Honey-Bearing Plants. — 628. Bee Diseases in Michigan.

**VARIOUS ANIMALS.** — 629. The Rearing of Reindeer in Canada.

#### IV. — FARM ENGINEERING.

**AGRICULTURAL MACHINERY AND IMPLEMENTS.** — 630. Co-operative Societies for the Use of Machinery and Materials used in Mechanical Tillages, for the Assistance of German Agriculture. — 631. SCHMIDT Tractor, specially constructed for Marshy Ground. — 632. — Apparatus for extracting Oily Matter by Ethyl Trichloride.

#### VI. — AGRICULTURAL INDUSTRIES.

**INDUSTRIES DEPENDING ON PLANT PRODUCTS** — 633 Relation between the Nitrogenous Substances in Barley and the Value of Barley in Brewing — 634. Utilisation of Tobacco Waste in the Manufacture of Nicotine Extracts and for Fertilising Purposes Experiments in South Africa — 635 Some Factors affecting the Quality of ripe Olives sterilised at high Temperatures. — 636. Rubber Latex for Paper Making.

**INDUSTRIES DEPENDING ON ANIMAL PRODUCTS** -- 637 Investigations on Milking Machines: their Efficacy, Advantages in Labour Saving, and their Sterilisation, — 638 Investigations on the Chemistry of Milk and Dairy Products, made in the United States — 639 Investigations on the Bacteriology of Milk and Dairy Products, made in recent Years in the United States. — 640 Influence of Surroundings and Temperature of Incubation on the Bacterial Count of Milk — 641. Variations of certain Characters of the Patty Matter in Buffalo and Cow-Milk corresponding with Change of Season and Feeding. -- 642 The reciprocal Application of the Numerical Indices of the Characters of the Fat in Cow Butter and in 'Ghee' (clarified Buffalo Butter) -- 643. Manufacture of Cheese of the Roquefort Type with Cows Milk in the United States.

#### PLANT DISEASES.

##### I. — GENERAL INFORMATION.

**LEGISLATIVE AND ADMINISTRATIVE MEASURES FOR THE PROTECTION OF CROPS.** — 644. Decree of December 21, 1921, No. 15198 sanctioning the Regulations relating to Plant Diseases in Brazil. — 645 Decree of January 26, 1922 prescribing the Measures of Control of Diseases and Animal Parasites of Plants in the Regency of Tunis.

### III. — DISEASES DUE TO FUNGI BACTERIA AND OTHER LOWER PLANTS.

#### a) GENERAL.

**RESISTANT PLANTS.** — 646. Persian "Black-Wheat" (*Triticum dicoccum* var. *persicum* resistant to Fungus Diseases. — 647. "Rubin" an early, rust-resistant Spring Wheat, for central Sweden.

**MEANS OF CONTROL.** — 648. Sugar-Sorghum and its rust-resistant Qualities — 649. Use of "Cambisan" in the Control of various Fungus Diseases of Rubber — 650. Means of Fungus Prevention in the Preservation of Acorns and Beech-mast

#### b) SPECIAL.

**PARASITIC DISEASES OF VARIOUS CROPS.** — 651. *Bacterium flaccumfaciens* n sp. injurious to Beans in South Dakota. — 652. Potato Disease in Argentina — 653. *Peronospora trifoliorum* found in Italy on Lucerne of Argentina Origin. — 654. *Botryditiplodia Theobromae*, a Deuteromycete injurious to the Cotton Plant (*Gossypium punctatum*) in Dahomey — 655. Diseases and Pests of Cinnamon in Ceylon — 656. The Mucedinea, *Botrytis vulgaris* on the ornamental Liliaceae, and in its latent Form on Rose Bushes in Italy — 657. *Cytosporina citrifera* n sp a Deuteromycete destructive to Orange, in Italy. — 658. *Tricothecium candidum*, a Mucedinea, injurious to Apples in Italy — 659. *Dothiorichia Sannini* n sp a Deuteromycete causing Scab ("Rogna") on Pomegranates in Italy. — 660. Fungi injurious to the American Grape in Sicily.

### IV. — WEEDS AND PARASITIC FLOWERING PLANTS.

661. — The Macrolepidopteron, *Papilio leratii*, a natural Means of controlling *Asclepias curassavica*, a Weed growing in New Caledonia.

### V. — INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

**GENERALITIES.** — 662. Biological Observations on the Larvae of the Coleopteron, *Tenebrioides mauritanicus*. — 663. Scale Insects observed on Orchidaceae in Colorado. — 664. Insects injurious to Crops in Brazil

**MEANS OF CONTROL.** — 665. The Introduction into Italy of the Hymenopteron *Aspidiotiphagus lounsburyi*, an endophagous Parasite of the "bianca-rossa" of citrus Trees (*Chrysomphalus dictyospermi*).

**INSECTS ETC. INJURIOUS TO VARIOUS CROPS.** — 666. South African Maize Pests — 667. Pests of *Sorghum vulgare*, in India. — 668. Insects Injurious to Sainfoin, in Sicily and Tunisia. — 669. *Heliothis armigera* (Cotton boll-worm) a Macrolepidopteron causing Damage in ratooned Cotton-fields in South Africa. — 670. *Homalonotus coriaceus*, injurious to the Coconut Palm in Brazil. — 671. Pests of the Cacao in Grenada. — 672. *Glyphodes*

*umonalis* a Microlepidopteron destroying Jasmine in the Department of Var — 673. *Eriophyes* spp, Mites Injurious to the Fruits of the Fig-Tree and of *Rubus* new to California — 674 Pests of the Date-palm in Mesopotamia — 675 Observations on an Affection of the Date Palm known under the name of "Doud" in North Africa — 676 The Fir-Needle Beetle (*Polydrosus pilosus*), in Switzerland — 677 The Grey Pyralis of the Larch (*Steganoptycha pimcolana*), injurious to the Siberian Pine and the Mountain Pine, in Switzerland — 678 Damage caused by the "White Fir Beetle" (*Pissodes piceae*) in Switzerland

## CONTENTS

### ABSTRACTS.

### AGRICULTURAL INTELLIGENCE.

#### I. — GENERAL INFORMATION.

- DEVELOPMENT OF AGRICULTURE IN DIFFERENT COUNTRIES. — 679. Report of the California Department of Agriculture for the Period ending December 31, 1921. — 680. Review of the Agricultural Situation in North West Morocco — 681. Agriculture in Sergipe (Brazil) Note from the President, Dr. José Joaquim Pereira Lobo. — 682. Notes on the Agricultural Conditions in the Italian Colonies.
- AGRICULTURAL EXPERIMENTS. — 683. Importance of Technical Supervision on Sugar Plantations.
- AGRICULTURAL ORGANIZATION. — 684. The "Office Régional Agricole" in the South of France.
- EXHIBITIONS, COMPETITIONS, CONFERENCES. — 685. The National Agricultural Conference in the United States — 686. The Smithfield Club Show in London and its Lessons

#### II. — CROPS AND CULTIVATION.

##### a) GENERAL.

- AGRICULTURAL METEOROLOGY — 687. Correlation between the Temperature and the Dates of Flowering in New England, U. S. A
- SOIL PHYSICS. — 688. Methods of Studying the Concentration and Composition of the Soil Solution. — 689. Use of various Culture Media in characterising Actinomycetes.
- METHODS OF CULTIVATIONS. — 690. Depth for Sowing Grass and Clover Seed. — 691. Studies on the Decomposition of some Common Green Manuring Plants at different Stages of Growth in the Black Cotton Soil of the Central Provinces, India. — 692. The Effect of Straw on the Biological Soil Processes — 693. The Influence of Wheat Straw on the Accumulation of Nitrates in the Soil — 694. Experiments on the Season for the Application of Sodium Nitrate and on the Behaviour of Leguminous Crops after the Application of Nitrogenous Manure. — 695. The Influence of varying Amounts of Sulphur in the Soil. — 696. Nitro-Cultures and their Distribution in Canada.
- AGRICULTURAL BOTANY CHEMISTRY, etc. — 697. The Food Plants of the Philippines. — 698. Stigmas of certain Plants adapted to the Germination of Sugar Cane Pollen. — 699. Analysis of Fijian Wild Cane (*Saccharum officinarum*), var. (?) Roots of *Cordyline terminalis*, Exudation from *Myoporum platycarpum*, and some Australian Fruits.
- INTERNAT. INST. OF AGRIC. *Internat. Review of Science and Practice of Agriculture.* Year XIII, No. 7. Rome, July, 1922.

- 700. Hydrocyanic Acid in Sudan Grass. — 701. Vitamine Content of Vegetable Oils. — 702. Changes in the Composition of Pepper (*Capsicum annum*) during the Growth Period. — 703. Action of Selenium on Plant Growth and Modifications due to Radio-Activity. — 704. Growth and Correlation in Sea Island Cotton.
- PLANT BREEDING. — 705. Problem of Maize Selection in the Colony and Protectorate of Kenya. — 706. Recommendations for the Improvement by Selection of *Agave Sisalana*. — 707. Yellow Stripes on the Leaf, a Hereditary Character of Maize.
- CEREALS AND SEED CROPS. — 708. Manitoba Wheat in Algeria.
- FORAGE GRASSES, ETC. — 709. Experiments with Fodder Plants in South Africa, and their Chemical Composition. — 710. Lucerne in Tucumán, Argentina. — 711. Grasses of agricultural Value in Southern Rhodesia. — 712. *Pennisetum purpureum* as a Forage Crop.
- FIBRE CROPS. — 713. Experiments in the United States with Meade Cotton, Upland Long Staple Variety, to Replace the Sea Island Variety. — 714. The Behaviour of Pima Cotton when grown under different Conditions of Soil Moisture and available Plant Food in the United States.
- RUBBER, GUM AND RESIN PLANTS. — 715. Rubber Content of North American Plants. Special Investigations with the *Asclepia* spp. and *Apocynum* spp. — 716. Cover Crops on Young Rubber Plantations in Malaya, and the Advantage of growing *Centrosema Plumieri* (Bötfly Pea) and *Mimosa Invisa* (Giant Mimosa).
- SUGAR CROPS. — 717. Germination and Preservation of Sugar Cane Pollen. — 718. Sugar Cane Varieties at Porto Rico
- STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL PLANTS. — 719. Tea Seed Production of Java and Sumatra. — 720. General Survey of the Cultivation of the Vanilla Bean, and its Preparation for Commercial Use. — 721. Chaulmoogra Oil from *Taraktogenus Kurzii* and its Medicinal Value as a Leprosy Cure. — 722. Alkaloidal Content of Leaves and Stems of Ipecacuanha from the Federated Malay States.
- FRUIT GROWING. — 723. Cultivation of Lemons in Argentina — 724. Superior Italian Cherry Varieties. — 725. Plum Growing in California and Methods employed for Drying the Fruits.
- FORESTRY. — 726 Price paid to Producer and Price charged to Consumer for Wood in France.

### III. — LIVESTOCK AND BREEDING.

#### a) GENERAL

- HYGIENE OF CATTLE. — 727. Supposed Poisoning of Sheep by Button Grass (*Eleusine acgyptiaca*). — 728. Poisoning of Cattle by the Prussic Acid in Sorghums. — 729. Control of Tuberculosis in California. — 730. Warts on Horses and Cattle. — 731. Investigations on Infectious Abortion in Cattle and Swine in the United States. — 732. Investigations on the Use of Vaccines prepared with *Bacillus ovisepticus*. — 733. Diseases in domestic Birds transmissible to Man. — 734. Spirochaetosis in Rabbits. — 735. Effectiveness of Tetrachloride of Carbon against *Uncinariae* (*Nematoda Strongylidae*) in Dogs.
- FEEDS AND FEEDING. — 736. Feeding and Contact Experiments with St. John's Wort (*Hypericum perforatum*) in New South Wales. — 737. The Mannitol-Producing Organisms in Silage. — 738. Malted Grain Sickness of Cattle considered as one of the Illnesses due to Malnutrition.
- STOCK BREEDING. — 739. The Application to Stock-Breeding of some new Views concerning Heredity.
- BREEDING. — 740. Livestock in Eritrea.

**b) SPECIAL.**

- HORSES.** — 741. The Philippine Horse. — 742. The Proportions of the Trotter.
- CATTLE.** — 743. Cost of Maintaining Milch Cows in Michigan. — 744. The Water Buffalo in the Northern Territory of Australia. — 745. Advantages of Heavy Feeding of Milch Cows.
- SHEEP.** — 746. Shropshire Sheep ; Distribution during recent Years and their Value for Crossing. — 747. Data to Serve as a Basis for the Development of a Systematic Pastoral Industry on Cyrenaica. — 748. Sheep-Breeding in the Ancient Daunia (Italy) and the "Carapellosi" Sheep.
- PIGS.** — 749. Progress in Pig Breeding in England. — 750. The large Black Pig in England. — 751. Effect of Rationing on the Development of Pigs.
- POULTRY.** — 752. The Rate of Growth of the Domestic Fowl. — 753. Nutrient Requirements of growing Chicks. — 754. Clover Flour and Grape-Pip Flour in Poultry Feeding. — 755. Duck Hybrids. — 756. Problems of Incubation. — 757. Poultry Rearing in Cyrenaica. — 758. Poultry Feeding Methods employed by Experiment Stations in the United States
- BEEKEEPING.** — 759. Bee-Keeping in Tasmania.
- SERICULTURE** — 760. Acceleration of the Development of the Silk-Worm

**IV. — FARM ENGINEERING.**

- AGRICULTURAL MACHINERY** — 761. Pump for Calzoni-Parenti Hydraulic Presses. — 762. Consumption of Coal and Electricity in Machine Threshing.

**V. — RURAL ECONOMICS.**

763. Cost of producing Wheat on 481 Farms in the States of North and South Dakota, Minnesota, Kansas, Nebraska and Missouri for the Crop Year 1919 — 764. The Cost of Production of Wheat, Beet, Potatoes and Milk in France.

**VI. — AGRICULTURAL INDUSTRIES**

- INDUSTRIES DEPENDING ON PLANT PRODUCTS** — 765. Copper in Light Wines — 766. Administration of the Economic Poison Law in California — 767. Distillation Experiments in the Preparation of Otto of Roses.
- INDUSTRIES DEPENDING ON ANIMAL PRODUCTS** — 768. Cost of Milk Production in Maryland, U. S. A. — 769. Dairy Inspection in California — 770. Investigation on Lactose Ferments in Cream which has a "Yeasty" Flavour — 771. Experimental Cheese-Making Institute at Lodi. — 772. A good Type of Mixed Cheese : the "Vittoria" of the Andria School of Agriculture (Province of Bari) — 773. Bacteria in Butter. — 774. Dairy Products Investigation Schemes Carried on by the Agricultural Experiment Stations in the United States. — 775. Unusual Odour of Wholesome Meat in the Refrigerator.
- AGRICULTURAL PRODUCTS ; PRESERVING, PACKING, TRANSPORT, TRADE.** — 776. The Preservation of Forage by Means of Electric Current.

## PLANT DISEASES.

III. — DISEASES DUE TO FUNGI  
BACTERIA AND OTHER LOWER PLANTS.

GENERAL. — 777. Fungi in Catalonia, Spain. — 778. The Mechanism of the Parasitic Action of *Penicillium glaucum* and of *Mucor stolonifer*.

MEANS OF CONTROL. — 779. Control of Diseases and Pests in California. — 780. The Control of Pear Scab in the Cape Province, South Africa.

PARASITIC DISEASES OF VARIOUS CROPS. — 781. Wart Disease of Potatoes (*Synchytrium endobioticum*) observed in South Africa. — 782. *Urocystis Bolivari* n. sp. a Ustilaginea Parasitic on Perennial Ray-Grass in Spain. — 783. *Fomes* sp. Root Disease of Rubber in Malaya. — 784. *Sclerotium cepivorum*, a Garlic Disease called "boixat" in Catalonia, Spain. — 785. American Gooseberry Mildew (*Sphaerotheca mors-Uvae*) reported from Piedmont, Italy. — 786. *Fusicladium* sp. and *Entomosporium* sp. on Loquat in the Cape Province, South Africa. — 787. *Cenangium Abietis* an Ascomycete injurious to Spruce Pine in Switzerland.

## IV. — WEEDS AND PARASITIC FLOWERING PLANTS.

788. Control of *Orobanche crenata* on Beans. — 789. Mistletoe on the Spruce Pine in Switzerland.

## V. — INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

GENERAL. — 790. Some Injurious Neotropical Weevils (Curculionidae). — 791. Observations on *Tortrix viridana* in Spain.

RESISTANT PLANTS. — 792. Meade Cotton resistant to Boll Weevil (*Anthonomus grandis*) in the United States.

MEANS OF CONTROL. — 793. *Upupa epops indica*, and its Utility in India.

INSECTS ETC. INJURIOUS TO VARIOUS CROPS. — 794. Unidentified Dipteron on Lucerne in Italy. — 795. "Murda" Disease of Pepper Plants caused by an unidentified Mite. — 796. The Gall Form of Vine Phylloxera observed for the first Time in New South Wales. — 797. "The Tukra" Disease of Mulberry caused by *Phenacoccus hirsutus* in Bengal.

EDITORIAL STAFF OF THE BUREAU OF AGRICULTURAL INTELLIGENCE  
AND PLANT DISEASES.

## CONTENTS

### FIRST PART: ORIGINAL ARTICLE.

F. CORTESE. — Problems of Cotton Growing . . . . . pag. 927

### SECOND PART: ABSTRACTS.

## AGRICULTURAL INTELLIGENCE.

### II. — CROPS AND CULTIVATION.

#### a) GENERAL

AGRICULTURAL METEOROLOGY. — 798 Phenological Observations in Holland in 1921 — 799 Data regarding the Distribution and Intensity of Hail in Bulgaria.

SOIL PHYSICS — 800. The Soil Fauna of Agricultural Land — 801. Influence of Salts on the Bacterial Activities of Soils. — 802. Influence of *Azotobacter* added to the Soil on Plant Growth — 803 Nitrogen Fixation in Ericaceae. — 804. The Micro-organisms of Sulphification.

TILLAGE AND METHODS OF CULTIVATION — 805. Researches on the Efficacy of Deep Tillage and on the Distribution of the Roots of certain Plants in different Strata of Soil. — 806. Application of Electricity to Cultivation.

MANURES AND MANURING. — 807. The Effect of Gypsum on Soil Reaction — 808. Herbaceous Growth of Arborescent Plants for the Production of Manure and Forage in Cuba. — 809. Sweet Clover as a Green Manure.

#### b) SPECIAL

AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS — 810. The Nitrogenous Compounds in Lucerne Hay — 811. The Chemical Composition of Plants as a Basis for the Estimation of their Water Requirements — 812. Influence of Conditions of Humidity on the Growth of Sainfoin Seeds Unhusked and Husked, respectively — 813. Absorption of Ions of Aluminium through the Root System of Plants. — 814. Experiments on the Use of Artificial Light in the Growth of Plants, in Germany. — 815. Influence of X-rays on dry Seeds and germinating Seeds

PLANT BREEDING. — 816. The Applicability to the Problems of Plant Genetics of Morgan's Theory of the Mechanism of the Chromosomes -- 817. Genetic Selection of the Wheats "Blanchetta" and "Gentil rosso", at Andria in Apulia (Italy) — 818. Natural Hybrids of Wheat × Rye at Saratov (Russia). — 819. Study of the Hybrids, Red Rustproof (*Avena sterilis*) × Black Tartarian (*Avena orientalis*), in the United States. — 820. The Improve-

INTERNAT. INST. OF AGRIC. *Internat. Review of Science and Practice of Agriculture* Year XIII, No. 8. Rome, August, 1922.

ment of Sorghum by Crossing and Selection in the United States. — 821. Correlation between the Colour of the Spermoderm in Pea and the Shape of the Seeds. — 822. Self-Pollination and Cross-Pollination in the Coconut Palm. — 823. The Improvement of the Sugar-Cane by Selection, in the Philippines. — 824. The Improvement by Crossing and Selection of the Raspberry (*Rubus Idaeus* etc.) and the Blackberry (*Rubus fruticosus* etc.) in the United States.

AGRICULTURAL SEEDS. — 825. Rapid Determination of the Germinating Power of Seed.

CEREALS AND PULSE CROPS — 826. "Trigu biancu", "Trigu arrublu" and "Trigu moru". Varieties of Wheat grown in the Province of Cagliari, Sardinia.

STARCH CROPS. — 827. Potatoes in the Islands of Chiloé (Chili).

FIBRE CROPS, ETC. — 828. Problems of Cotton Cultivation for Discussion at the International Congress at Rio de Janeiro (October 1922). — 829. Problems of Cotton Planting

VINE-GROWING — 830. Principal Vines grown in Dalmatia — 831. The Question of American Stock for the Vines of the Trentino

FORESTRY. — 832. The Renewal of Chestnut Woods in France

### III. — LIVESTOCK AND BREEDING.

#### a) GENERAL.

HYGIENE — 833. Poisoning by Green Carobs, in Italy — 834. Colloidal sulphur in the Treatment of Sarcoptic Mange in Horses. — 835. Spirillae, Pathogenic Agents of Contagious Abortion in Germany — 836. Cases of Contagious Abortion in Cows without Demonstrable Cause — 837. The Treatment of Sterility of Non Pathological Origin in Cows — 838. Diseases of Zebu in Madagascar — 839. *Necator suillus* n. sp., a New Swine Parasite — 840. A Disease of Young Pigs consequent on Dry Years

FEEDS AND FEEDING — 841. Calculation of the Money Value of the Nutritive Unit — 842. The Insufficiency of Lime and Phosphoric Acid in the Feeding of Animals.

STOCK BREEDING — 843. The Stock Breeding Establishment at Sidi Tabet, Tunis — 844. Methods of Castration of Domestic Animals

#### b) SPECIAL.

HORSES. — 845. Survey of Horse-Breeding in Roumania — 846. Observations on Twin Gestation in Mares. — 847. Limits of the Breeding Age in Thoroughbred Mares.

CATTLE — 848. The Stock of Cattle in Morocco — 849. The Importation of Tropical Cattle into the Northern Territory of Australia — 850. Studies on Beef Production. — 851. Butter-Fat Percentage of Cow's Milk increased for two Days by Partial Milking. — 852. Effect of Temperature on the Fat Percentage of Milk — 853. The Zebu of Madagascar regarded as a Meat Producer

SHEEP — 854. Notes for a History of the French Breed of Sheep of Charmoise. — 855. Sheep of Catalonia, Spain — 856. Romney Marsh Sheep in New Zealand — 857. The present Condition of Merino Sheep Breeding in Australia

GOATS — 858. The Effect of Food upon the Fat Content of Goat's Milk.

PIGS — 859. "Large Black" Pigs in Italy. — 860. Remarkable Specimens of Pigs of the Iberian Breed, in Spain. — 861. The Effect of Breeding on Immature Sows.

POULTRY. — 862. The Bresse breed — 863. A little known South American Species of Fowl, the "Colloncas de Aretes" of Chili (*Gallus inauris*). — 864. Egg laying Characteristics of the Hen

BEE-KEEPING. — 865. Studies on Bee-keeping in the United States. — 866. The Winter Care of Bees.

#### IV. — FARM ENGINEERING.

AGRICULTURAL MACHINERY AND IMPLEMENTS. — 867. Electricity and Agriculture. — 868. Posts supporting Agricultural Electric Wires

#### VI. — AGRICULTURAL INDUSTRIES.

INDUSTRIES DEPENDING ON PLANT PRODUCTS. — 869. New Type of Copal Oil from the Belgian Congo.

INDUSTRIES DEPENDING ON ANIMAL PRODUCTS. — 870. Apparatus and Methods of Analysis for Dairy Industries. — 871. Correlation between the Quality of Cream and Butter and the Yeasts and Oidia they contain.

### PLANT DISEASES.

#### I. — GENERAL INFORMATION.

LEGISLATIVE AND ADMINISTRATIVE MEASURES FOR PLANT PROTECTION — 872 Various Measures adopted in France for the Control of the Potato Colorado Beetle (*Leptinotarsa decemlineata*). — 873 Ministerial Order of May 27, 1922 announcing the Precautions to be taken against the Propagation of the "Argentine Ant" (*Iridomyrmex humilis*), in Italy.

#### II. — DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

874 "Gummosis" in Chestnut Wood.

#### III. — DISEASES DUE TO FUNGI BACTERIA AND OTHER LOWER PLANTS.

##### a) GENERAL.

GENERAL. — 875. Bacterial Plant Diseases in the Isle of Luzon in the Philippines.

RESISTANT PLANTS. — 876. Resistance of Wheat X Rye Hybrids to *Fusarium nivale*. —

877. Resistance of Oats, Varieties Red Rustproof (*Avena sterilis*), Black Tartarian (*A. orientalis*) and their Hybrids to *Ustilago Avenae* and *U. laevis* in the United States. — 878. General Immunity to Diseases of Potatoes in Island of Chiloé, Chili. —

879. *Cassia siamea*, Leguminous Plant used as Green Manure, immune to Diseases and Pests, in Cuba. — 880. Resistance of Sugar Cane to Disease especially to Fiji Disease in the Philippines. — 881. "Pavana" an Italian Grape resistant to Oidium.

MEANS OF CONTROL. — 882. Control of Ink Disease and Attacks of the Ascomycete *Endothia parasitica* in the Renovation of Chestnut Woods in France.

DISEASES OF VARIOUS CROPS. — 883. *Helminthosporium* sp. on Rice in Madras. — 884. *Sarna* (*Oospora Scabies*) on Potatoes in the Island of Chiloé (Chili). — 885. Diseases of Cotton. — 886. *Thielaviopsis paradoxa*, a Hyphomycete injurious to Coconut Palm in the Presidency of Madras. — 887. *Sclerotinia carunculoides*, n. sp. Discomycete on Mulberry in South Carolina. — 888. The Mucedin *Monilia cinerea*, found on the Leaves of the Peach Tree in Piedmont, Italy.

#### IV. — WEEDS AND PARASITIC FLOWERING PLANTS.

889. — Biological Studies on *Cuscuta Epithymum* var. *Trifolii*.

#### V. — INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

GENERAL. — 890 New African Coleoptera. — 891. The Cochineal Insect *Icerya purchasi* in Provence.

MEANS OF CONTROL — 892. Organisation of the Control of the Cochineal Insect *Icerya purchasi*, in Morocco, in 1921 — 893. *Leucopis* sp., a destructive Dipteron of *Aphis sorghi* and *A. gossypii*, Injurious respectively to *Sorghum vulgare* and to Cotton in the Anglo-Egyptian Sudan. — 894. Natural Enemies of Mango Leaf-Hoppers (*Idiocerus* spp.) in India. — 895. Natural Enemies of *Tortrix viridana* in England — 896. Control of Insect Pests of Potato in Island of Chiloé (Chili).

INSECTS ETC., INJURIOUS TO VARIOUS CROPS — 897. The "Colorado Beetle" (*Leptinotarsa decemlineata*), in the Gironde — 898 The "Bombyx dispar" (*Lymantria dispar*) Injurious to Apricot Trees, in Vaucluse

## CONTENTS

### FIRST PART: ORIGINAL ARTICLES.

Dr. JOAQUIM WANDERLEY DE ARANJO PINHO Note on the Cocoa Tree in the State of Bahia (Brazil). Pag. 1169

### SECOND PART: ABSTRACTS.

### AGRICULTURAL INTELLIGENCE.

#### I. — GENERAL INFORMATION.

RURAL HYGIENE — 1010 Action of Vitamines

AGRICULTURAL EXPERIMENTS — 1011 Influence of the Weight and Size of Seeds on Yield.

#### II. — CROPS AND CULTIVATION.

##### a) GENERAL.

AGRICULTURAL METEOROLOGY — 1012 Critical Period of Wheat as regards Rain

SOIL PHYSICS, CHEMISTRY AND MICROBIOLOGY. — 1013. Plant Indicators of Soil Types. — 1014 The Control of Soil Moisture by Means of Auto-Irrigators. — 1015. Factors influencing the Determination of Sulphate in Soil — 1016 Presence of Cobalt and Nickel in arable Soil. — 1017 Tests of Vesuvian Bacteriology. — 1018 The Influence of Moisture and Soluble Salts on the Bacterial Activities of the Soil — 1019 Influence of Hydrogen-ion on Growth of Azotobacter — 1020. The Carbon and Nitrogen Relations of the Nitrite Ferment. — 1021. Effect of Tree Products on the Bacterial Activities in Soil: Ammonification and Nitrification — 1022 Soil Fatigue

IRRIGATION. — 1023 Irrigation in Tunisia

MANURES AND MANURING — 1024. Production of Phosphoric Acid by the Method of Electric Condensation and Precipitation. — 1025. Enriching Extract of Phosphoric Acid by means of successive Decompositions of Phosphonites. — 1026 Experiments on the Fertilising Value of "Supra" disintegrated Phosphate, in Belgium — 1027. Assimilability of various Phosphate Manures. — 1028. The Supply of Nitrogen for Agriculture in Germany. — 1029. Fixation of Atmospheric Nitrogen, and the Fabrication of Nitrogenous Manures in Egypt. — 1030 Fertilisers for Beans

##### b) SPECIAL.

AGRICULTURAL BOTANY, ETC. — 1031. Seeds and Plants introduced by the Agricultural Department of the United States. — 1032. New and noteworthy Philippine Plants. —

INTERNAT. INST. OF AGRIC. *Internat. Review of Science and Practice of Agriculture*  
Year XIII, No. 10. Rome, October, 1922.

1033. Nickel and Cobalt in living Organisms. — 1034. Chemical Analysis of the Gramineae, *Panicum maximum*, *P. jumentorum* and *P. barbinode*. — 1035. Action of Soluble Salts of Lead on Plants. — 1036. The Role of Manganese in Plants. — 1037. Influence of Lime on Germination. — 1038. Effect of Röntgen Rays on Cells of *Vicia faba*. — 1039. The Effect of Iron and Aluminium Salts upon the Growth of Maize. — 1040. Growth of Plants in Relation to Soil Humidity — 1041. Reaction in Fresh Water caused by Aquatic Plants — 1042. Effect of Transpiration on Absorption of Salts by the Plant. — 1043. Process of Assimilation of Phosphoric Acid in Plants.
- SEEDS. — 1044. On the Catalysis of Seeds. — 1045 Weight and Size of Seeds as Factors influencing Yield.
- CEREALS AND PULSE CROPS — 1046. Hard Moroccan Wheats. — 1047 Is the Transplantation of Maize advantageous? — 1048. Competition in Rice Transplanting in the Province of Novara (Italy) in 1921 — 1049 The Encouragement of the Growth of Lupins in Germany. — 1050 Action of various Manures on Beans
- FORAGE CROPS, MEADOWS AND PASTURES. — 1051. Brazilian Forage Plants — 1052. Varieties of Maize for Silage Purposes. — 1053 Composition of the Forage Plants "Guinea Grass" (*Panicum maximum* and *P. zementorum*) and "Malojillo" (*P. barbinode*) grown at Porto Rico — 1054. Para Grass (*Panicum barbinode*) and Paspalum (*Paspalum dilatatum*) in the Island of Guam. — 1055 Forage Sorghums — 1056. Experimental Growth of "Ghessab" (*Pennisetum spicatum*) in Sicily. — 1057 Mangolds in Combination with Maize.
- OIL PRODUCING PLANTS. — 1058. Olive-Growing in the South-West of the United States.
- SUGAR CROPS — 1059 Comparative Values of various Nitrogenous Manures for Sugar Cane Growing in Java — 1060 Use of the Refractometer in the individual Examination of Sugar Beets
- AROMATIC PLANTS, ETC — 1061 Chests of Red Cedar (*Juniperus virginiana*) for Protecting Clothing against Damage by Moths (*Tineola bischella* Humme) — 1062 Belladonna and Foxglove cultivated in the Province of Florence, Italy — 1063 Wormseed (*Chenopodium ambrosioides*)
- HORTICULTURE. — 1064. Vegetable Growing in the Island of Guam
- FORESTRY. — 1065 Cultivation of Citrus Fruits in Rhodesia
- VINE GROWING. — 1066. Vine-Growing in Alsace
- FORESTRY — 1067. Mangrove Swamps in the Dutch Indies — 1068 Wooden Chests made of *Juniperus virginiana* for Protecting Clothes against Insect Attack.

### III. — LIVESTOCK AND BREEDING.

#### a) GENERAL.

- HYGIENE OF CATTLE. — 1069. The Screw-Worm Fly (*Chrysomya macellaria* Fabricius) and other Diptera parasitic on Stock in the United States. — 1070. Splenic Inflammation of Pigs in Prussia and the Causes of its increased Frequency.
- ANATOMY AND PHYSIOLOGY. — 1071 Experimental Contribution to the Knowledge of the "Working Conditions" of Draught Animals under different Dietary Conditions.
- FEEDS AND FEEDING. — 1072. Rules for Feeding Cattle. — 1073 Use, as Cattle Food, of certain Waste Products from Chick-peas, Peas and Beans.
- STOCK BREEDING. — 1074. Improvement of Stock Breeding in Morocco.

b) SPECIAL.

- CATTLE.** — 1075 The Work of the Central Syndicate for the Exportation of Charolais Cattle. — 1076. The Identification of Cattle by Means of Nose-Prints. — 1077. Studies on Reproduction of Cattle. — 1078 Some Results of Feeding Milch Cows at Experiment Stations in the United States. — 1079 Comparison of early, medium and late maturing Varieties of Silage Maize for Milk Production — 1080 Quantity of Feed consumed by a Heifer from Time of Birth to Lactation Period.
- GOATS.** — 1081. The Goat as an Economic Factor
- PIGS.** — 1082 The Pasturing of Pigs
- POULTRY REARING.** — 1085. Distribution of Enzymes in the Alimentary Canal of the Chicken.
- BEE KEEPING.** — 1084 Insulating Capacity of Double-Walled Bee-Hives — 1075 "La Loque" (*Bacillus alvei*), a Bee Disease
- SILKWORM REARING** — 1086 Sericulture in Libya — 1087 Value of Maintaining an even Temperature during the Incubation of Silkworm Eggs — 1088 Forced Hatching of Silkworm-Eggs with shortened Hibernation - 1089 On the Relation of Pebrine Infections in Bombyx Moths and in the Eggs at rest and just before Germination (Expediency and Desirability of Testing a modified Method of preparing Silkworm-Eggs) — 1090 Duration of Virulence of the Pathogenic Agent of Jaundice in the Silk-worm
- FISH BREEDING** -- 1091 Pisciculture in Switzerland in 1921
- VARIOUS ANIMALS** 1092 American Mole as Agricultural Pests and Fur Producers

IV. — FARM ENGINEERING.

- AGRICULTURAL MACHINERY** -- 1095 Power Farming in Egypt

V. — RURAL ECONOMICS

1094. Receipts and Payments in the Cultivation of Ghessabi in Sicily - 1095 The Feed Cost of a Heifer from Birth until the Beginning of the first Lactation Period — 1096 Variations in the Cost and Sale Prices of Butter before the War, and from 1918 to 1921, in the United States

VI. — AGRICULTURAL INDUSTRIES.

- INDUSTRIES DEPENDING ON PLANT PRODUCTS** -- 1097 Composition of Wines of Laos and Lees of Wine 1098 Should Apples for Cider Making be washed? — 1099. The Olive Oil Industry in Greece - 1100 Manufacture of Tapioca Starch at Porto Rico -- 1101. The Value of Ohio Wheats for Bread-Making — 1102 Manioc Bread. — 1103 The Clarification of unfermented Fruit Juices. — 1104. Analyses of Italian Preserved Fruits
- INDUSTRIES RELATING TO ANIMAL PRODUCTS.** — 1105. Studies on the Biology of Lactic Acid Bacteria. -- 1106 Commercial Production of Butter in the United States

## PLANT DISEASES.

## III. — PARASITIC DISEASES (BACTERIA, FUNGI AND OTHER CRYPTOGAMS.)

GENERAL. — 1107. Correlation between the Aluminium Content of Sugar Beet and Bacterial Infection.

RESISTANT CROPS. — 1108. Various Plants introduced into the United States resistant to certain Diseases and Pests.

PARASITIC DISEASES ON VARIOUS CROPS — 1109. The Ascomycete *Ophiobolus cariceti*, as the Cause of Take-all of Cereals and Grasses. — 1110. Observations made in New York State on the Take-all Disease of Cereals and Grasses (*Ophiobolus cariceti*). — 1111. Moroccan Durum Wheats liable to Rust — 1112. Diseases and Pests of the Olive Tree, in the United States. — 1113. Diseases and Pests of the Cacao in Bahia, Brazil. — 1114. Leaf-Spot Disease of Tobacco caused by *Phyllosticta Nicotiana* in North Carolina. — 1115. *Soja max*, *Dahlia rosea* and *Cosmos bipinnatus*, new Hosts of *Bacterium Solanacearum* in North Carolina. — 1116. *Bacterium Solanacearum* injurious to various cultivated Plants in the Philippines. — 1117. *Fusarium* sp., a Deuteromycete injurious to the Tomato Plant in North Queensland. — 1118. *Cercospora Melongenae* n. sp., a Hyphomycete injurious to the Egg Plant in the Philippines — 1119. Banana Freckle (*Phoma Musae*) in the Philippines — 1120. *Penicillium expansum*, Stem End Rot of Apples, in California. — 1121. Observations on the Erysiphaceae, *Microsphaera quercina*, *Sphaerotheca mors-uvae* and *Oidium farinosum*, in Italy

## V. — INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

GENERAL. — 1122. Observations on the Coccids of Egypt

INJURIOUS INSECTS, ETC. — 1123. *Vespa germanica* and *V. vulgaris*, Hymenoptera injurious to the Ghessab (*Pennisetum spicatum*) in Sicily — 1124. *Calligrapha exclamatoris* and *Mordellistena pustulata*, Beetles injurious to *Helianthus* spp. in Manitoba, Canada. — 1125. *Pyrausta nivalis*, a Microlepidopteron parasitic on the Nymphaeaceae, *Nelumbo lutea* and *N. nucifera* in the United States — 1126. The Banana Weevil (*Cosmopolites sordidus*), injurious also to Abaca (*Musa textilis*), in the Philippines — 1127. *Tetranychus yothervi*, a Mite injurious to the Avocado and other Plants in Florida — 1128. The Beetle *Ips Pini* as a primary Pest of *Pinus densata* and *P. resinosa* in Minnesota.

## CONTENTS

### ABSTRACTS.

### AGRICULTURAL INTELLIGENCE.

#### I. — GENERAL INFORMATION.

- DEVELOPMENT OF AGRICULTURE IN DIFFERENT COUNTRIES** — 1129 Development of natural Resources in Portuguese East Africa — 1130 Agriculture in Nigeria in 1921 — 1131 Agriculture in the State of Bahia, Brazil
- RURAL HYGIENE** — 1132 Destruction of Mosquitoes by Bels
- AGRICULTURAL EXPERIMENTS** — 1133 Effect of Aluminium Salts and of Acids of various Strengths on the Development of Plants in Water Culture

#### II. — CROPS AND CULTIVATION.

##### a) GENERAL.

- AGRICULTURAL METEOROLOGY** — 1134 Effects of a dry, warm Year on Wheat Crops grown at Verrieres
- SOIL PHYSICS** — 1135 The Treatment of Soil with Ferrous Sulphate and its Influence on the Soil Solution obtained by the Lapman Pressure Method. — 1136 Zinc as a normal Constituent of Soil under Cultivation and of Plants — 1137 Base Exchange and Alkalinity in Egyptian Soils — 1138 Determination of the Organic Matter in the Soil — 1139 Partial Sterilisation of the Soil — 1140 Action of Carbonic Acid Liberated by Micro-Organisms in improving Arable Land — 1141 The Influence of Plants upon Oxidation Processes in the Soil — 1142 The Classification of Soil Moisture.
- MANURES AND MANURING.** — 1143 Experiments in the Improvement of Alkaline Soils by the Application of Gypsum and other Methods. — 1144 Injurious Action of Composts — 1145 The Value of Tetrphosphate as a Fertiliser — 1146 Various Grades of Basic Slag, in Great Britain. — 1147 Potassic Deposits in Poland — 1148. Pot Culture Tests on the Availability of Potassium in Greensand Composts. — 1149. The Nitrogen Industry in Germany — 1150 The Transformation of Ammonia into Urea — 1151. The Decomposition of Ammonium Nitrate by Heat. — 1152. Borax in Fertilisers and its Effect on Potato Growth. — 1153. Chili's Sulphur Supply

##### b) SPECIAL.

- AGRICULTURAL BOTANY, CHEMISTRY AND PHYSIOLOGY OF PLANTS** — 1154 Accidental Flora imported in Wool and the Question of Acclimatization in Germany. —
- INTERNAT. INST. OF AGRIC.** *Internat. Review of Science and Practice of Agriculture* Year XIII, No. 11. Rome, November 1922.

1155. Study on the Pollen of Fruit Trees. — 1156. Characteristic Proteins in Maize. — 1157. The Part played by Respiration in the Decrease of Carbohydrates in Leaves during the Autumn Colour Change. — 1158. Non-Symbiotic Germination of Orchid Seeds. — 1159 Variation in the Manganese Content of Leaves according to their Age.
- PLANT BREEDING — 1160. The Role of Chemistry in the Improvement of Plants.
- SEEDS. — 1161. Development of mutilated Seeds of Maize.
- STARCH CROPS. — 1162. Influence of the Weight of the Potato Set on the Crop. — 1163. The supposed Degeneration of the Potato.
- FORAGE, CROPS, ETC. — 1164 Cultivation of Lucern in Sub-Tropical Semi-Arid Regions. — 1165 Experiments with Mangolds.
- TEXTILE PLANTS, ETC. — Brazilian textile Plants.
- PLANTS YIELDING OILS, ETC — 1167. Observations on the Flower of the Olive Tree. — 1168. Experimental Stations for Oleaginous Plants in French African Colonies. — 1169. Less known vegetable Oils and Fats of Japan.
- RUBBER, GUM AND RESIN PLANTS — 1170 Pressure in the Roots of *Hevea brasiliensis*
- CAMPHOR PLANTS. — 1171. Camphor in Tonkin
- RESINOUS PLANTS — 1172. Copal.
- STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL PLANTS — 1173. The Chemistry and Manufacture of Tobacco. — 1174. Temporary and permanent Shading of Cocoa, Coffee, etc. in the Belgian Congo. — 1175 The Cultivation of *Pyrethrum* in Switzerland. — 1176 Acclimatisation in France of *Spartina Townsendi*, a Soil-binding Forage and Paper yielding Plant
- HORTICULTURE — 1177. Study on the Pollen of Fruit Trees — 1178. Influence of Grafting on the Resistance of Aurantiaceae to Cold
- VINE GROWING — 1179 Phylloxera-Resistant Vinestock. — 1180 On the Sensitiveness of Grafted Vines to Frost.
- FORESTRY — 1181. Programme of the Swedish State Institute of Experimental Forestry for the period 1922-26. — 1182. The Distillation of Stumps and Logging Waste of *Pinus ponderosa* (Western Yellow Pine).

### III. — LIVESTOCK AND BREEDING.

#### a) GENERAL.

- HYGIENE. — 1183 "Peste de Cezar" (Encephalomyelitis in the Horse) in the State of Paraná (Brazil) — 1184. Should Milch Cows which react against Tuberculin be slaughtered? — 1185. Skin-diseases among Livestock at Porto Rico — 1186. Sheep-Killing Dogs in the United States. — 1187. Experimental Research on an Eruptive Disease of the Goat observed in Greece.
- ANATOMY AND PHYSIOLOGY. — 1188. Chemical Composition of the Bodies of Domestic Animals — 1189 Investigation on Milk "Retention" in the Cow.
- FEEDS AND FEEDING. — 1190 Food Value of Oats and Tares as Green Forage Hay or Silage. — 1191. Digestibility of several Lupine Products after their Bitterness had been removed, and their Utilisation in Milk Production. — 1192. Coconut Cake as Feed for Milch Cows and Breeding Stock generally. — 1193. The Asphodel as a Food for Animals. — 1194 Albumen replaced by Urea in the Food of Milk producing Animals.

**PIG BREEDING.** — 1195. Swine Heredity: Swine as a Reserve Stock for Experiments in Heredity.

**BREEDING CATTLE** — 1196. Investigations on the Growth of Livestock.

*b) SPECIAL*

**CATTLE.** — 1197. Zebu Selection for Milk Production in Brazil — 1198. Comparative zootechnical Value of the Zebu and the Ox. — 1199. The pure-bred Cattle of Glan-Donnersberg (Palatine) — 1200. Cattle-Breeding in the Province of Padua. — 1201. Feeding Tests on half-breed Store Cows in Calf

**SHEEP.** — 1202. Casual Flora imported into Germany in Wool and the Question of Acclimatization

**PIGS.** — 1203. Feeding Tests on Swine: Acorns as compared with Oats and Barley Seconds. — 1204. Rations for Swine.

**POULTRY REARING.** — 1205 The Rearing of Geese in the United States

**FISH BREEDING** — 1206. Carp Breeding in Auvergne

**IV. — FARM ENGINEERING.**

**AGRICULTURAL MACHINERY** — 1207 The Production of Agricultural Machinery in the Ukraine. — 1208 Power Cultivation of Vineyards — 1209 Experiments with Milking Machines — 1210. New Method for Draining Lees — 1211. Experiments in electro-culture — 1212 "Micropump" R. Lefi — 1213 A New Seeder

**V. — RURAL ECONOMICS.**

1214 — The Cost of manual Labour in the Production of Milk — 1215 Comparison between Net Costs and Profits of French Breeding in 1913 and 1921 — 1216 Reduction in the Values of Farm-Products

**VI. — AGRICULTURAL INDUSTRIES.**

**INDUSTRIES RELATING TO PLANT PRODUCTS** — 1217 Presence of Aischnic in Grapes, Musts and Wines due to the Use of Insecticides -- 1218 Disappearance of free Sulphurous Acid in preserved Apple Juice — 1219 Maraschino prepared with pure Blastomycetes — 1220. The Sugar Industry in Russia before and after the War — 1221. The Distillation of Stump-Wood and Logging Waste of Western Yellow Pine.

**INDUSTRIES RELATING TO ANIMAL PRODUCTS** — 1222 Relationship between the Concentration of the Hydrogen Ion and the Number of Bacteria in Milk. — 1223 The Accuracy of Weinzierl's Test for Determining the Contamination of Milk by Fæcrement. — 1224 Contamination of Milk by defective Corking of Bottles — 1225 The Milking Machine and the Hygienic Qualities of Milk — 1226 The Foaming of Cream — 1227. Calculation of the Quantity of Yeasts and Moulds and their Relationship to the Pasteurisation of Cream for making Butter. — 1228. Common Defects in Butter and how to avoid them. — 1229. Specific Gravity of the Serum of diluted Butter Milk

**PRESERVATION, PACKING, TRANSPORT AND TRADE IN AGRICULTURAL PRODUCTS.** — 1230. The Production of Sauerkraut. -- 1231. Frauds in the Algerian Wool Trade, and their Prevention. — 1232. The Export of Cake in France

## PLANT DISEASES.

## III. — PARASITIC DISEASES (BACTERIA, FUNGI AND OTHER CRYPTOGAMS.)

GENERAL. — 1235 Influence of Temperature on the Distribution of Grain Smut of Sorghum (*Sphacelotheca Sorghi*) in India.

PARASITIC DISEASES OF VARIOUS CROPS — 1234. The Sleepy Disease of the Tomato in Great Britain and the Channel Isles — 1235 *Mycosphaerella citrullina*, an Ascomycete injurious to various Cucurbitaceae, in Japan. — 1236 *Bacillus Carolovorax*, the Cause of Soft-Rot in cultivated Violets in England — 1237 *Thielaviopsis paradoxa* a Hyphomycete injurious to the Coco-Nut Palm in Florida -- 1238. *Rosellinia Caryac* n. sp. an Ascomycete injurious to the Juglandea *Carya ovata*. in Michigan

## IV. — WEEDS AND PARASITIC FLOWERING PLANTS

1239 *Lilium Bulbiterum* as a Weed in Prussia

## V -- INSECTS AND OTHER INJURIOUS INVERTEBRATES

GENERAL — 1240. Lepidoptera in Cyrenaica

MEANS OF CONTROL — 1241 *Sigalphus biterpes*, a Hymenopteron parasitic of *Laia rufimana* the "Bean Bruchus", in England. — 1242 *Apantheles melanoscelus*, a hymenopterous Braconid Para-site of "bombyx disparate" (*Porthetria dispar*) imported from Sicily to New England. — 1243 The Control of *Heteroderes amphicollis* and other Coleoptera injurious to Tobacco in Cuba — 1244. New Method for the Control of *Aleurocanthus woglumi*, a Rhynchote injurious to Fruit Trees in Cuba

INSECTS AND OTHER LOWER ANIMALS INJURIOUS TO VARIOUS CROPS — 1245 *Sitona hispidula*, *S. sulcitrons* and *S. crinita*, Weevils injurious to Leguminous Crops in Britain. — 1246 *Hypopta caestrum* a Macrolepidopteron injurious to *Asparagus* in France — 1247 The "Bombyx Disparate" (*Porthetria dispar*) injurious to Oaks in Morocco.

## CONTENTS

### ABSTRACTS

### AGRICULTURAL INTELLIGENCE.

#### I — GENERAL INFORMATION.

DEVELOPMENT OF AGRICULTURE IN DIFFERENT COUNTRIES — 1248 White Settlement and World Agriculture. — 1249 Agriculture in Greece

AGRICULTURAL EXPERIMENT — 1250 Agricultural Experimentation in Assam during the Year ending March 31, 1922 — 1251 Experimental Work in Progress in the Laboratories, Rothamsted Experimental Station, England.

#### II. — CROPS AND CULTIVATION.

##### a) GENERAL.

AGRICULTURAL METEOROLOGY — 1252. The Climate of the mountainous Regions of Minas Geraes (Brazil) in Relation to agricultural and zootechnical Conditions — 1253 Effect of Meteorological Factors on the Quality and Quantity of Wheat produced in Argentina. — 1254 Effect on the Yield of Wheat of Variations in the Degree of Humidity of the Soil during and after the critical Period.

SOIL PHYSICS — 1255. Report of the Study of the Soil of the First Egyptian Zone (Chabija) en 1921. — 1256. Report of a Study of the Soil of the Territory of the Right Bank of the Diahlah (Mesopotamia). — 1257 The Aeration of Soil as an Ecological Factor. — 1258. The Effect of Soil Drying upon soluble Soil Constituents — 1259 Experiment on the Leaching of Nitrate Salts of Calcium, Sodium and Potassium from the Soil by Rain, in Finland. — 1260 Experiments on the free Acidity of mineral Soils — 1261. Clark's Hydrogen Electrode Apparatus and its Determinations of the Concentration of the Hydrogen Ions in the Soil. — 1262. Possible Correlation between the Fertility of Soils under Rice and their Titration Curves. — 1263. The Effect of the Magnesium and Calcium in Limestone upon the Chemical Composition of the Soil and on Plant Behaviour. — 1264. Distribution of the Phosphorous Ion in the upper Layers of the Soil in Relation to Vegetation and the Addition of various Salts. — 1265. The Oxidation of the Sulphur in Alkaline Soils. — 1266 Bacteria connected with the Oxidation of Sulphur in the Soil : Media used for the Isolation of Sulphur Bacteria from the Soil. — 1267. Biochemical Methods for Determining the Fertility of Soils. — 1268. The Effect of the Application of various Salts upon the Nitrogen-Fixing Properties of Soil.

**MANURES AND MANURING.** — 1269 The Agricultural Value of Sea Sand. — 1270. The Effect of the continuous Application of Chemical Fertilisers upon Soil Reaction. — 1271. Manuring Fish Ponds: Exchange of Bases in the Soil. — 1272. Waste Water from Wool-Washing, as a Source of Fertiliser. — 1273 Influence of Humic Acids on the Assimilation of Phosphoric Acid — 1274 The Agricultural Value of the insoluble mineral Phosphates of Aluminium, Iron and Calcium. — 1275. The Effect of Mineral Phosphate upon Phosphatic Acid Absorption and the Productivity of Maize and Sorghum — 1276. On the Alkalinity of Basic Slag — 1277. The Potassic Deposits of Catalonia, Spain. — 1278. Progress of Nitrogen Fixation after the War. — 1279 Advantages of Bicarbonate of Ammonia as a Fertiliser, both from the Point of View of its Production and of its Use. — 1280. Chloride of Ammonium as Manure — 1281. Arsenic and its Uses in Agriculture — 1282. Selection and Treatment of Waters for Spraying Purposes.

#### b) SPECIAL

**AGRICULTURAL BOTANY, PLANT CHEMISTRY AND PHYSIOLOGY** — 1283 On the Presence of Cobalt and Nickel in Plants — 1284 The Biochemistry of *Sclerotinia cinerea* — 1285. Ammonia as a basal and a final Product in the Transformation of Nitrogen by Plants.

**PLANT BREEDING (SELECTION).** — 1286 Pedigree Selection of Gottingen Rye (Germany).  
**SEEDS.** — 1287. Trade in Forage in Belligerent Countries

**CEREALS AND PULSE CROPS** — 1288. Autumn Cereals in Morocco. — 1289. On the Tillering of Wheat. — 1290. Cultivation of Barley in England. — 1291. Rice Planting in Sarawak. — 1292. Food Pulse Crops in Morocco. — 1293 Effect of different Reactions on the Growth of Soy Beans and the Formation of Nodules.

**FORAGE PLANTS, MEADOWS AND PASTURES** — 1294 Good Forage Grasses of Southern Rhodesia. — 1295 Species of *Rumex* in Grasslands — 1296. Effect of Crude Phosphates and Basic Slags on the Quality of Hay and Pastures

**TEXTILE AND FIBRE CROPS, ETC.** — 1297. Fibre Crops in Morocco. — 1298. Cotton in French Africa. — 1299. The Technological Value of the New Hebrides Cottons.

**PLANT YIELDING OILS, ETC** — 1300. Production of Seeds and Vegetable Oils in Bessarabia. — 1301 Growth of the Castor-Oil Plant in Morocco. — 1302. Growth and Preparation of the Castor-oil Plant in Brazil. — 1303 Tanning Substances of Indo-China. — 1304. Tanning Substances of Tonkin.

**RUBBER GUM AND RESIN PLANTS** — 1305 Cultivation of the Soil in Rubber Plantations. — 1306 The Root System of Hevea in various Soils — 1307. Practical Examination of the Bark of Hevea and its Importance in Tapping. — 1308. Individual Variations in the Starch Content of the Bark of *Hevea brasiliensis*. — 1309. On the Presence of Quercetin and Sugar in the Latex of Hevea according to different Circumstances. — 1310. A Note on the Sugar in Hevea Latex.

**SUGAR CROPS.** — 1311. Palm Sugar in Cambodia.

**STIMULANT, AROMATIC, NARCOTIC AND MEDICINAL PLANTS.** — 1312. The Cultivation of Tobacco in the Crimea. — 1313. Nicotine Content of South African Tobacco.

**HORTICULTURE.** — 1314. Notes on the Cultivation of the Pineapple.

**FRUIT GROWING.** — 1315. Cherry Growing in Wisconsin, U. S. — 1316. The Date Palm in Iraq.

**VITICULTURE.** — 1317. The Viticultural Wealth of Greece. — 1318. Deep Ploughing of the Soil and its Effect on Vine Chlorosis.

**FORESTRY.** — 1319. Storage of Coniferous Tree Seed — 1320. An Investigation into the Relation between Height, Growth of Trees and Meteorological Conditions. — 1321. Colonial Timbers and the Work of the Bordeaux Colonial Institute — 1322. Atlas Cedar Wood Oil.

### III. — LIVESTOCK AND BREEDING.

#### a) GENERAL

**HYGIENE.** — 1323. Pathogenetic Consequences of Feeding Cattle on Cakes made of Cacao-Bean Shells — 1324. Lupinism in Horses. — 1325. John's Disease (chronic bacterial Dysentery or Paratuberculosis) of Cattle — 1326. Disease of newly-Born Rabbits.

**FEEDING OF CATTLE.** — 1327. Present Cost in Germany of a Kilogram of Starch or its Equivalent in different Feeds as compared with that before the War — 1328. Comparison between Calcium Chloride and other Calcium Salts as a Stock Feed.

**BREEDING.** — 1329. Hybridism in the Genesis of tame Races of Birds.

#### b) SPECIAL

**HORSES.** — 1330. Horse-Breeding in Dalmatia and Bucovina — 1331. Horse Breeding in Hungary — 1332. The Importance of Breeding heavy Draught Horses in Westphalia.

**CATTLE.** — 1333. Development of Cattle Breeding in the Palatinate: the Simmenthal Breed and the Place it Occupies in the Agriculture of the District. — 1334. The Advisability of continuing to Breed dual Purpose Cattle in Bavaria — 1335. Experiments on Cattle Feeding in the United States Experiment Stations. — 1336. The Milch Cow in Italian Agriculture. — 1337. Dairy Cow Breeding and Milk Production in Holland.

**GOATS.** — 1338. Effect of Variations in the daily Yield and in the Diet on the Composition of Goat's Milk.

**PIGS.** — 1339. Rearing young Pigs without Milk Rations. — 1340. Summer Pig Breeding in Germany. — 1341. Breeding Autumn farrowed Pigs in the United States — 1342. Development and Feeding of pure bred Yorkshire Pigs from the Time of Weaning to the Beginning of Fattening: Observations at the Lodi Experimental Cheesemaking Institute — 1343. A Bavarian Breed of Pigs in Process of Extinction. — 1344. Studies of the present Position of Pig Breeding in Germany and in Australia. — 1345. New Methods of Pig-Breeding in Germany as the most effective Means of increasing Meat and Fat Production. — 1346. The Expediency of rearing Swine at Grass in South Germany. — 1347. Lucern as Pasture for Pigs, in Germany — 1348. Rape as a valuable Pasture for Pigs. — 1349. Pig-Breeding in Tuscany: its Difficulties and the Means of Promoting its Development.

**POULTRY REARING, ETC.** — 1350. The Effect of Cod-Liver Oil on « Leg Weakness » in newly-hatched Chickens. — 1351. The « Type » in Poultry Breeding — 1352. Intensive Chicken Rearing.

**PISCICULTURE.** — 1353. Pisciculture Value of a Stream — 1354. Advantages of Keeping Carp in Ricefields for Fertilizing the Soil. — 1355. Piscicultural Research in Germany. — 1356. Eels and their Place of Breeding.

## IV. — FARM ENGINEERING.

AGRICULTURAL MACHINERY — 1357. Development of Electro-Agriculture in the Province of Bologna. — 1358. Palm Oil as Motor Fuel — 1359. Experiments in Mechanical Flax Carding

FARM BUILDINGS. — 1360 Farm Garages.

## V. — RURAL ECONOMICS.

1361 Value of Animal Products in Relation to Crop Yield since 1919 in the United States  
1362 Plant Foods and human Foods in Germany

## VI. — AGRICULTURAL INDUSTRIES.

AGRICULTURAL INDUSTRIES — 1363 Types of Wine produced in the Trentino — 1364. The "Deferrage" of Wines (Report of the Governor General of Algeria) — 1365. Studies on Wine Mould and Mouldiness in Cellars in Italy — 1366. Process of Fermenting Maize Stalks for making Acetone, Alcohol and volatile Acids. — 1367. Possibilities of the Plant Growth of the damp Tropical Areas for Suppling Materials for liquid Fuel. — 1368. The Sweetness of Cane and Beet Sugars and their Value for Jam Making. — 1369 Bread making with Manioc Flour — 1370 Production of Olive Oil in Greece. — 1371. The Grape Syrups and Preserve Industry.

DAIRYING. — 1372 Dairy Production in Czecho Slovakia. — 1373 Condition of the Dairy Industry in Hungary. — 1374. Scientific and economical Study on Milk Refrigeration with Drum Refrigerators -- 1375 Bitter Milk at a late Stage of Lactation. — 1376. Manufacture and Composition of Milk Powder and its possible Influence on the Preservability of whole Milk Powders. — 1377. Bacterial Contents of Milk Powder. — 1378. Technological and economical Data on some Types of Italian Cheeses. — 1379. The Food Value of Bull Beef.

AGRICULTURAL PRODUCTS; PRESERVING, PACKING, TRADE — 1380 Resolutions passed by the Congress of the National Federation of the Live Stock Trade.

## PLANT DISEASES.

II. — DISEASES NOT DUE TO PARASITES  
OR OF UNKNOWN ORIGIN.

1381. Injuries produced on Weymouth Pines and other Plants due to Causes of chemical Origin. — 1382 "Chlorosis" in Pineapples — 1383 "Chlorosis" in the Vine and deep Ploughing

## III. — DISEASES DUE TO FUNGI, BACTERIA, AND OTHER LOWER PLANTS.

GENERAL. — 1384 Biochemistry of *Sclerotinia cinerea* — 1385 Experiments on Vegetable and Animal Plant Pests carried out [at the Experimental Station of Rothamsted, England.

PARASITIC DISEASES OF VARIOUS CROPS. — 1386. A New Potato Disease observed in Morocco. — 1387. New Micromycetes Living on *Cinchona* spp., in Indo-China. — 1388 *Photia braccata*, an Agaric injurious to cultivated Lavender in France. — 1389 *Mollisia Earliana*, an Ascomycete injurious to Strawberry Plants, in Ontario, Canada — 1390 Diseases and Pests of Pineapples. — 1391 The White-Rot of the Vine (*Coniothecium Diplothele*) in Switzerland

## IV. — WEEDS AND PARASITIC FLOWERING PLANTS

1392. The Crucifer *Nasturtium austriacum*, a new Weed in the United States — 1393 The Labiate *Salvia Elthobis*, a Weed new in Oregon. — 1394. Arsenic in the Control of Weeds

## V. — INJURIOUS INSECTS AND OTHER LOWER ANIMALS

GENERAL. — 1395. Boll Weevil and other Causes of Damage to Cotton Crops in the United States.

MEANS OF CONTROL. — 1396. Observations on *Ithone fusca*, a Neuropteran preying on injurious Beetles, in Australia. — 1397. New Hymenopterous parasitic on injurious Insects. — 1398. Natural Enemies of Insects injurious to Forest Trees, in the United Provinces,

India. — 1399. Disinfection of Cotton seed with Chloropicrin. — 1400. Selection and Treatment of Waters for Spraying Purposes — 1401. Pests of Rice at Sarawak, Borneo.

INSECTS AND OTHER INVERTEBRATES INJURIOUS TO VARIOUS CROPS — 1402. Observations on *Caulophylus latinasus*, a Beetle injurious to Seeds, in Florida, Georgia and South Carolina. — 1403. *Apophyllia murina* and another undetermined Beetle reported for the first Time as injurious to various Crops, in Rhodesia. — 1404. Phylloxera of the Vine in Greece — 1405. Pests of the Date Palm in Irak — 1406. Animal Pests of *Artocarpus* spp., and *Tectona grandis*, in the Dutch Indies.

#### EDITORIAL STAFF OF THE BUREAU OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES.

*Chief of Bureau* : Dr. JULES-MICHEL SAULNIER.

GENERAL INFORMATION.

- 1 - **The Effect of a Variation in Milling on the Digestibility of Wheat Flours.** --  
LANGWORTHY, C. F. and HOLMES, A. D., in *Proceedings of the National Academy of Sciences of the United States of America*, vol 7, No 4, pp 110-123 Washington, April 1921

HYGIENE

The shortage in the World's food-supply in 1917 made the collection and correlation of data concerning human nutrition of the outmost importance and many questions were re-examined in the hope of providing additional data of value.

Extensive investigations into the chemical composition, digestibility and nutritive value of wheat and wheat products have already been made by European investigators and in the United States (1). Investigations made by the Office of Home Economics of the U. S. Department of Agriculture undertaken with the co-operation of the Maine and Minnesota Agricultural Experiment Stations included studies in the digestibility of wheat flours prepared in a variety of milling conditions from wheat grown in similar climatic, seasonal and soil conditions. The results obtained showed that the protein of white flour (72 % extraction) was 88.1 % digested; that of entire wheat flour (85 % extraction) was 81.9 % digested, and that of graham flour (100 % extraction) was 76.9 %.

In 1917, the U. S. Food Administration requested the Office of Home Economics to obtain additional data concerning the relative digestibility

(1) U. S. Department of Agriculture, Office Expt. Stations Bulletin 85 (1900); 101 (1901); 126 (1903); 143 (1904); 150 (1905)

of flours representing a series of extractions from the same lot of wheat. The flours studied were prepared from the wheat mixture provided to the flour-millers by the U. S. Grain Corporation late in 1917 and consisted of the following: choice hard spring (largely Marquis), 20 % — spring, 25 % — velvet chaff, 15 % — slightly smutty spring, 25 % — durum, 10 % — Kansas and Oklahoma, 5 %. The milling rates adopted were: 54-70-85-100 % of wheat or in other words the flours were those known in commerce as "patent", "standard patent", "whole wheat" and "graham". The digestibility tests were conducted with healthy young men, of whom some were accustomed to much and others to comparatively little exercise: There were 139 of these tests and the experimental periods were from 15 to 25 days in length and subdivided and regarded as separate and successive three-day experiments. The diet consisted of bread, oranges, sugar with tea or coffee. The following table summarizes the results.

*Summary of Experiments on the Digestibility of Wheat Flours.*

Kind of flour used	Number of experiments	Amount of bread eaten per man per day	Digestibility of entire ration			Digestibility of Bread Protein	Digestibility of Bread Carbohydrate
			Protein	Fat	Carbo- hydrate		
		Grammes	Per cent	Per cent	Per cent	Per cent	Per cent
54 % flour	43	600	87.8	96.5	98.8	87.7	99.7
70 % "	42	564	90.1	96.1	99.0	90.1	99.9
85 % "	21	472	87.1	96.9	97.5	87.1	98.5
100 % "	33	663	84.2	93.9	95.0	84.2	94.4

Thus the maximum of digestibility was shown by the 70 % flour, that of the 54 % flour was slightly greater than that of the 85 % flour, while the digestibility of the 100 % flour was the lowest. The results are in accord with those obtained in earlier experiments. The fat content of the diet was equally well digested, digestibility being almost complete, except in the case of the 100 % flour, when it reached 93.9 % only.

The 54 % and 70 % flours did not tend to produce constipation; the 85 % and 100 % flours produced a somewhat freer movement of the bowels but no marked laxative effect was noticed.

2 - The "Bacteriophagous" Microbe (1). - D'HERELLE, F., in *La Nature*, No. 2478, pp. 219-222. Paris, Oct. 1, 1921

An account, for general use, of the present state of information with regard to the bacteriophagus microbe discovered by the Author, who makes the following statement:

(1) Several Studies on the bacteriophagous microbe were analysed in R. April 1920, No. 439 and R. April 1921, No. 399. — Others have appeared in the *Comptes rendus de la Société de Biologie*, Vol. LXXXIV, 1921, pp. 3. (E. WOLLMAN). — 5 (L. MARTIN) — 275, 750, 751, 753, 755 (A. GRATIA) — 276, 278, 280, 745, 747, 748 (J. BORDET and M. CIUOA) — 339, 384, 538, 803, 908 (F. D'HERELLE) — 467, 468, 755 (J. MAISIN) — 708 (G. ELIAVA and F. POZERSKI) — (F. D'HERELLE and E. ELIAVA) — 847 (R. BRUYNOCHE and J. MAISIN). (*Ed.*)

" The facts observed in bacillary dysentery are the following

A sample of the dejecta are taken for each day from the onset of the malarly till the end of convalescence. Each sample is mixed with broth and passed through a Chamberland filter: all the microbes which can be seen under the microscope remain in the filter, the filtered liquid is clear and remains so indefinitely if preserved aseptically; it is apparently sterile.

For the sake of clearness, I take a chance example from the notes on a series of experiments

The case of Victor Ker was tested during a period of 30 days, giving 30 samples of dejecta filtrate, one for each day

Thirty tubes of dysentery bacillus culture are taken and a drop of each of the 30 filtrates added to each tube and all the tubes submitted to a temperature of 37° C in the stove. After twelve hours the following results are reached.

Tubes 1-6, no change; the broth is turbid as in the case of a normal culture of dysentery bacteria

Tubes 7-18, perfectly clear

Tubes 19-30, turbid as tubes 1-6

Hence a strange phenomenon is to be noted in tubes 7-18 the dysentery bacteria have been dissolved without leaving a trace. How has this been caused? It cannot be the drop of added filtrate. It is to be concluded that from the seventh to the eighteenth day the patient's dejecta contained some element which destroys and dissolves the dysentery bacteria.

If we now enquire whether there is any correlation between the state of the patient and the presence of the solvent principle in the excreta, we see that from the seventh day onwards the blood has disappeared from the stools and the patient's condition has rapidly improved, by the eighteenth day the cure was complete. The presence of the solvent principle has been coincident with the cure. An investigation of a large number of cases has shown that the phenomenon is constant, not only in bacillary dysentery but also in typhoid, fowl typhus and even in maladies without intestinal symptoms, such as hemorrhagic septicaemia in buffaloes and bubonic plague.

If the filtrate containing the principle which dissolves the dysentery bacteria is again examined and an infinitesimal quantity of the culture added instead of a drop - for example a thousand millionth part of a cubic centimetre, - after a few hours the bacilli are as completely dissolved as with a drop. What then is the nature of this bacteriocidal principle whose action is many thousand times more effective than any antiseptic, however powerful?

If a trace of the culture of dysentery bacilli which has become clear as a result of the action by the filtrate is taken and introduced into a new, very turbid culture of the same bacillus, within a few hours this second culture becomes clear and all the bacilli are dissolved. If a trace of this second dissolved culture is introduced into a third, this is in its turn dissolved also and the series can be continued indefinitely, for example a trace of the fourth dissolved culture causes dissolution in the fifth. Hence the principle which dissolves the bacteria reproduces itself and develops as a living germ."

If the culture of dysentery bacilli in the limpid state is examined under the highest form of microscopic enlargement no microbe is visible. The principle which dissolves the bacteria is a microbe of extreme minuteness, which escapes the closest filtration and is invisible under the microscope, an ultra-microbe in a word. These ultra-microbes are enumerated in the following manner:

Ten cubic centimetres of a broth culture rich in dysenteric bacilli are taken to which is added the filtrate containing the dissolvent principle so diluted as to contain one fiftieth thousandth part of a cubic centi-

metre of the filtrate ; this is shaken vigorously and immediately a hundredth part of a cubic centimetre is exposed uniformly on the surface of a solid tube. After heating in the stove at a temperature of 37° C. a layer of bacilli will be found on the solid medium, interspersed with 50 small circular fields in which the bacilli are dissolved. Each field represents a focus for the dissolution of bacilli, that is to say an ultra-microbe originally developed. This method of enumeration is the basis of all the experiments which have enabled the Author to study the activities of the ultra-microbe and to determine its function.

The result so far obtained may be briefly summarized as follows :

The principle which dissolves the microbes is an extremely minute ultra-microbe : its volume might be regarded as equivalent to that of a molecule of albumen. It is named by the Author *Bacteriophagum intestinale* or more simply " bacteriophage " and is itself a dependent parasite only able to develop at the expense of living bacteria which it penetrates by means of its property of secreting dissolvent principles. It reproduces itself after penetration into a bacterium ; utilizing for its growth the substance dissolved from the bacterium, it forms a colony of 15 to 25 elements. The bacterium gradually swells, assumes a globular form and then bursts, thus liberating the young ultra-microbes, each of which in turn becomes parasitic on a fresh bacterium.

There is only a single type of bacteriophagous microbe, which through habituation can become parasitic for a very large number of species of bacteria, quite possibly for all bacteria. Up to the present the Author has identified it in parasitic stocks for very different species — the bacilli of dysentery, typhoid fever, plague and staphylococcus to name only typical bacteria of human diseases. The faculty possessed by the bacteriophagous microbe of becoming parasitic for different species of bacteria corresponds precisely with the acquisition of a " virulence " which can be enhanced or diminished *in vitro*.

The normal habitat of the bacteriophagous microbe is the intestine and the Author has found it in the contents of the intestine of all the healthy animals he has examined both vertebrate and invertebrate. Here it lives at the expense of the normal bacteria to be found in the host. When a strange bacterium is introduced into the intestine, the bacteriophagous microbe becomes habituated more or less rapidly according to conditions and becomes parasitical for the invading germ. If this germ is pathogenic, the fate of the individual attacked depends upon the rapidity with which the bacteriophagous microbe becomes habituated. If habituation is immediate, the disease aborts before producing any morbid symptom, if delayed, the disease declares itself and the period of delay determines the duration of the illness. Convalescence begins only at the moment when the bacteriophagous microbe gets the mastery of the bacterium and if habituation does not take place at all the victim succumbs.

The question arises why is habituation sometimes retarded or checked. The answer is that environment exercises an influence upon the struggle favourable to one or other of the contending germs. For exam-

ple the bacteriophagous ultra-microbe is more sensitive than the bacteria to the reaction of the environment ; it cannot resist a degree of alkalinity or acidity which the bacteria can withstand with practical impunity. There is also another element, primordial in character, which gives the other side of the question. The bacteriophagous microbe is capable of assuming the quality of " virulence " as against a bacterium, but the bacterium when attacked does not remain passive but defends itself and can acquire immunity. The stages of the struggle between the bacteriophagous microbe and the bacterium are precisely similar to the stages of the struggle between the bacterium and the higher organism on which it is parasitic. The disease bacterium secretes a toxin which acts upon the cells of the infected subject, which replies by developing an antitoxin. The bacteriophagous microbe secretes a dissolvent diastase, or lysine which acts upon the bacterium, which replies by developing an antily-sine ; thus there is merely a descent in the scale of the contending entities.

Protection by the bacteriophagous microbe is not confined to affections of the intestine ; the ultramicrobe can also enter the circulatory system and function at any point in the organism. For example the author in cases of convalescents has succeeded in isolating and making cultures of bacteriophagous microbe stocks which dissolve the bacillus of bubonic plague.

Briefly the history of a case of infectious disease is a reflection of the process of the struggle which takes place in the organism between a disease bacterium and the bacteriophagous ultra-microbe.

But this is not all : every convalescent from a contagious disease carries in the intestine bacteriophagous ultramicrobes working against the disease bacterium, and distributes them with his excreta. He can thus " infect " his neighbours and immunity is as contagious as the disease itself. The author has frequently discovered that at the end of an epidemic all susceptible subjects who have escaped the contagion carry in the intestine the bacteriophagous microbe in the active state and in this way the idea of " contamination " by the bacteriophagous microbe has been brought home to him.

Thus the history of an epidemic is in the final analysis the history of a struggle between two active forces : the disease microbe, which at the beginning develops freely, and the bacteriophagous microbe whose virulence against the bacterium increases in the case of patients where conditions are favourable. Such patients recover, distribute the bacteriophagous microbe in active condition and the epidemic comes to an end when all susceptible individuals give it shelter in their organism. These facts have been demonstrated by studies of different forms of animal distempers such as fowl typhus, hemorrhagic septicaemia of buffaloes and rat-plague : the two last diseases were investigated in the Far East.

Hence a new fact emerges : antimicrobial immunity is heterologous in the susceptible animal ; the defence of the organism is secured by an ultra-microbe, parasitical upon the bacteria.

But as has been seen this ultra-microbe can be cultivated *in vitro*

and it is therefore possible to obtain as many cultures as may be required. If the observations made are in fact accurate and a susceptible animal is assured of immunity from the moment when the bacteriophagous ultra-microbe becomes habituated to parasitism upon the disease-producing microbe which is trying to invade the organism, it ought to be possible to reproduce the phenomenon at will. In this case it will merely be necessary to introduce into the susceptible organism a culture of the bacteriophagous microbe which has become virulent for any particular bacterium to cause the organism to become immediately proof against the disease which it causes.

Experiments made in fowl typhus and hemorrhagic septicaemia of buffaloes have in fact established this principle, for they have shown that,—

a) in epidemic conditions a single injection of a minimum quantity of a culture of the bacteriophagous microbe active in relation to a given bacterium produced immunity from the disease caused by it from the moment of the injection.

b) in non epidemic conditions immunity was acquired only after an incubation period varying according to the dose injected. In the case of hemorrhagic septicaemia in the buffalo immunity is attained after twenty days with a dose of a quarter of a cubic centimetre. After the injection of a single drop a buffalo weighing 250 kg. became immune in four days.

Experiments in connection with the curative properties of the ultra-microbe have also been made on similar lines in 100 cases of fowl-typhus and later in 7 cases of human bacillary dysentery. These have proved that the injection or ingestion of a minimum quantity of a culture of the bacteriophagous microbe, developed at the expense of the disease-causing bacterium, checks the progress of the disease at once, provided of course, that it is introduced at a time sufficiently near to its first onset to secure that the organic lesions are not of themselves severe enough to bring about a fatal issue, for the function of the bacteriophagous microbe is confined to the destruction of the bacteria. It has been noted above that at the end of an epidemic all the susceptible individuals who have escaped contagion are carriers of the bacteriophagous microbe destructive to the bacterium which causes the disease. This conception makes it possible to consider the possibility of a collective protection. It would seem that this purpose would be fulfilled by diffusing in the drinking water cultures of the bacteriophagous microbe in a state of activity, there being ample experience to shew that it is absolutely harmless for all living beings.

In this way it could be made certain that the bacteriophagous microbe destructive of the cause of the epidemic would be present in the organism of all susceptible individuals during the whole of the critical period.

What light is thrown on the phenomenon of phagocytosis by these new facts?

A study of the phenomena of protection must deal with three different conditions of the subject :

- 1) The animal naturally resistant.
- 2) The susceptible animal that has acquired immunity either naturally following on an attack, or experimentally following a vaccine treatment.

The above are the two conditions which have been considered by **METCHNIKOFF** and his fellow workers. They have recognized that protection in these two cases is secured by phagocytosis. It still remains necessary to consider the means of protection for:—

- 3) The susceptible animal that does not, or does not as yet, enjoy immunity.

The two following questions require to be answered.

Susceptible animals exposed to contagion do not in all cases contract the disease. what are the means of protection possessed by those which escape?

An animal attacked by a contagious disease of bacterial origin is cured and thus obtains protection: what are its means of protection between the onset of the malady and the moment when this immunity is established? In fact why does the cure take place?

Experiments upon the bacteriophagous microbe suggest the answer to these questions.

The heterologous immunity produced by the bacteriophagous microbe does not take the place of the homologous cellular immunity, for it functions at a time when the latter is not active; the first is dominant in the susceptible animal, the second in the resistant.

**New Institutes for Agricultural Experiment in Italy.** — **STRINGHER, V.**, in *Atti della R. Accademia dei Georgofili*, Series V, vol. XVIII, N° 2, pp. 64-82. Florence, April 1921 (1).

AGRICULTURAL  
EXPERIMENTATION

An account of the establishment during recent years of Institutes for Agricultural Experiment, founded by various Agricultural Associations and placed under the general supervision of the Ministry of Agriculture.

The "Stazione agraria sperimentale" at Bari has been at work since 1919: its main objectives are as follows.

a) The scientific study of the special problems of Agriculture in Southern Italy with particular reference to the application of physics, chemistry and biology thereto

b) Methods of protecting crops from vegetable and animal pests.

c) The publication of practical information concerning crops and agricultural industries of special interest in Apulia.

The State, Province, Municipality and Chamber of Commerce of Bari all contribute to the maintenance of the Institute with a total annual contribution of 93 000 *lire*. The local authorities provided the building and site; in addition the Ministry of Agriculture made a grant of 640 000 *lire* for initial capital expenses.

(1) See R. Oct-Dec. 1919, No. 1074 (Ed).

The " Istituto sperimentale di meccanica agraria " at Milan was opened on June 10, 1920 ; its chief duties, which are both agricultural and industrial, are the following :

a) To carry out studies and trials of machines and machine-plant used in agriculture, agricultural industries, soil improvement and irrigation either at the instigation of the Government or other Public Administrative Bodies, the request of manufacturers, etc., or on the direct initiative of the Institute.

b) The preparation of tests and the collection and coordination of essential elements in trials for juries at Competitions and Exhibitions of agricultural machinery.

c) Laboratory and open air research work leading to conclusions likely to be of assistance in the scientific and technical development of machines and machine-plants for agricultural industries.

d) The coordination of the work of the Institute with results obtained in similar institutions in other countries, by juries at Competitions and Exhibitions and by specialists, with reports thereon to the competent Ministries and to Institutions and other bodies interested.

e) To give technical advice with regard to machines, plant and agricultural industries.

The Ministry of Agriculture has made a grant of 100 000 *lire* for initial capital expenditure and allows 50 000 *lire* a year for maintenance ; the Province and Municipality of Milan each make grants of 10 000 *lire* annually. It has however to be recognized that, in order to carry out its functions on the lines laid down, the Institute will require much larger subsidies and these are likely to be forthcoming.

A Government Decree of June 8, 1920, established the " Istituto nazionale di genetica per la cerealicoltura ". Its duties are to conduct experiments to discover the best varieties of cereals for the different districts of Italy and to arrange for their distribution to the farmers. The Institute will have a total sum of about 8 500 000 *lire* at its disposal.

The Institute will have under its administrative and technical control :

a) Phytotechnical stations with trial and initial multiplication plots for Apulia, Sicily and Latium (attached to the Institute) ;

b) Local observation and trial plots ;

c) Multiplication plots ;

d) Plots for the maintenance of pure seed lines with offices for distribution attached ;

e) A museum of genetics at Headquarters.

The technical work of the " R. Stazione sperimentale di granicoltura " at Rieti will be coordinated with that of the new Institute.

The " Istituto di allevamento vegetale per la cerealicoltura " was originally founded at the " Scuola superiore di Agraria " at Bologna and recognized by the Ministry of Agriculture on June 10, 1920, which assigned to it a total annual subsidy of 50 000 *lire*. The special duties of this Institute are as follows :

1) Work for the improvement of the most important types of cereals grown in Italy, particularly wheat and kindred varieties ;

2) To bring about a more effective and complete employment of improved varieties :

a) by encouraging and carrying out, in cooperation with local agricultural associations and individual farmers, trials for the purpose of delimiting the most advantageous zone of culture for each variety ;

b) by encouraging and directing as occasion arises the local seed production in each zone so that as a general rule each district may be in the position of raising on its own soil the means of reproducing the selected varieties which it requires ;

3) To carry out from time to time selective tests in an appropriate milieu, of common established varieties of cereals at the request, or on behalf, of a contributory agricultural association ;

4) To complete the phytotechnical studies of the pupils of the Higher Agricultural School of Bologna by means of an appropriate practical and experimental apprenticeship.

The " Stazione sperimentale di maiscoltura " was founded at Bergamo on March 7, 1920, for the purpose of the improvement of maize culture and is mainly engaged on the following studies :

a) The physiology of the maize plant ;

b) Native and foreign varieties, selection and crossing ;

c) The value of the main product (grain) from the point of view of preservation, crushing and grinding, as food for men and cattle, industrial use (cake, alcohol, etc.) and as a marketable commodity ;

d) The waste products (stalks, straw, etc.) and how to use them to best advantage ;

e) The rotation systems best adapted to the crop, fertilizers, preparation of the soil, sowing and methods of cultivation, irrigation ;

f) The main difficulties in maize-culture and methods of control ;

g) Means of preserving the crops, etc.

A capital expenditure of 240 000 *lire* has been incurred and maintenance subsidies amount to 35 000 *lire*.

The station will also be in a position to deal with problems of selection for other cereals and especially for barleys for malting, and in addition experimental work on deterioration in maize will be undertaken.

The " Stazione sperimentale di Riscoltura " at Vercelli was started in 1908, and reorganized in 1917. It derives an annual income of 39 600 *lire* in addition to the premises and land required for the special work undertaken which is as follows :

a) To initiate, encourage and control experiments and demonstrations with the object of improving rice culture on a scientific basis so as to increase the value of the crop both in quantity and quality and also to improve other irrigated crops grown in rotation with rice ;

b) To keep abreast of the economics of rice-culture both at home and abroad, as a source of information and guidance to be communicated to farmers and other workers concerned, for the benefit of Italian production ;

c) To make contributions to the solution of the hygienic and social problems connected with rice culture ;

d) To make known by means of suitable peripatetic instruction the results of experimental and demonstrational work.

Funds amounting to 3 800 000 *lire* have recently been made available for this station.

The Experimental Station which was started at Lodi in 1871 was developed in 1919 into the " Istituto sperimentale di Caseificio ". The main object of this Institute is to carry out scientific and technological enquiries into questions related to milk and its derivatives with reference both to its use as a food substance and also to the dairying industry in order to obtain precise and definite information. At the same time it will undertake experiments of all kinds calculated to establish the best technical results combined with the greatest economic advantages, and encourage the dissemination of modern ideas on the science and technique of milk production by means of occasional courses of instruction, conferences and publications. In addition to the half million *lire* allocated for capital expenditure, the Institute has a total annual subsidy of 50 000 *lire*.

The " Stazione sperimentale del freddo " annexed to the " R. Scuola superiore di Agricoltura " at Milan has been at work since July 1, 1913. Its functions include :

a) The examination, for purposes of comparison, of machinery, equipment and substances (especially non-conductive) used in the industry ;

b) The study of the application of artificial chilling, especially as regards the preservation of perishables and the treatment of agricultural produce ;

c) Enquiries into means of transport in cold storage and their organization from the point of view of food supply and problems of importation and exportation.

The Station has a total annual revenue of 18 000 *lire* together with a capital grant of 50 000 *lire* from the Ministry of Agriculture

The " Stazione di batteriologia agraria " at Crema was instituted in 1914 and deals with the following questions :

a) The preparation and preservation of forage ;

b) The feeding of cattle from the point of view both of hygiene and production ;

c) The milk industry ;

d) Tobacco culture ;

e) The retting of flax and other plants used in the textile industry ;

f) The preparation and preservation of alcoholic beverages ;

g) The preservation of fruits, vegetables and animal products ;

h) Treatment by organic fertilizers ;

i) Microbial soil life with reference to its productivity and chemical constituents.

The Government makes an annual grant for maintenance of 30 000 *lire* and a group of local and district agricultural Associations makes a similar contribution. As a result of the contributions by different State

Departments and local Associations the Station is now definitely established and is about to spend 800 000 to 900 000 *lire* on the purchase of a farm with stallage for 50 to 60 cattle.

The "Stazione sperimentale di pollicoltura" at Rovigo was opened on June 28, 1917. The land and buildings and certain grants are provided by the Local Authorities and in addition the State made a contribution of 40 000 *lire* for initial expenditure and allows an annual grant of 25 000 *lire*. The scope of this Institution includes :

a) The improvement of the most suitable breeds of birds, both local and imported, by means of crossing and selection ;

b) The comparative study and the choice of breeds giving the best results as regard food value and egg production ;

c) The study of the most scientific and economical methods of breeding ;

d) The study of the diseases of poultry and the best means of prevention and cure .

e) Instruction and propaganda by means of short courses at the Institute, conferences and practical leaflets.

f) All other forms of work and study, instructional and experimental, contributory to the economic development of poultry farming in Italy. Additional funds are to be allocated to the Institute by the Ministry of Agriculture

Adequate grants have also been made to the following — the Laboratories of Agricultural Chemistry at the R Scuola Superiore di Apicoltura at Milan and the R Scuola superiore di Agricoltura at Portici, the Laboratory of Chemical Agricultural Technology at the "R. Istituto Superiore agrario sperimentale" at Perugia, the Laboratory of Agricultural Chemistry at the "R Scuola superiore di agricoltura" at Pisa and the independent Laboratories at Forli and Udine.

In brief the Italian Government has, during the economic and financial crisis following on the war, made a liberal and comprehensive provision for Agricultural Experiment similar to that made when the first Institutes for experimental work in Agriculture were founded in Italy during the period from 1870 to 1872.

#### 4 - Third International Congress of Household Economy Instruction, Paris, April 1922.

The International Federation for the development of Domestic Economy Teaching, which has its central Office at Fribourg (Switzerland), decided to hold in Paris, from the 18th to the 21st of April a 3rd International Congress of Household Economy Instruction with an Exhibition of equipment, material and methods. The two previous Congresses were held at Fribourg in 1908 and at Ghent in 1913.

A National French Committee has been formed in Paris for the local organization of this Congress with M. CHAMPETIER DE RIBES as Chairman and an office at 23 Rue Bertrand.

The following are the subjects for discussion at the Congress.

EXHIBITIONS;  
MEETINGS,  
CONFERENCES

*General Scope:* Organization, science and means of simplification of household work.

**First Section.**

**GENERAL POSITION OF HOUSEHOLD ECONOMY INSTRUCTION.**

1) *Household Economy Instruction in different Countries since the Ghent Congress.*

A. *Position immediately before the war.*

B. *Position during the war.*

Increased activity of women in national life through replacing men called up for military service. Observations made under these headings.

a) How have Household Economy Schools been carried on and worked during the War?

b) Have they been subsidized by the State or Municipality?

c) How have Household Economy Schools adapted themselves to the special conditions and what special services have they rendered, both national and local?

d) How far have members of the staff assisted in making good the shortage in food and fuel during the war?

e) Have the respective Governments and Local Authorities appreciated the services rendered and in what form has appreciation been expressed? — General results — marked development of women's sphere in political, economic and social life.

C. *Position at present time.*

General reconstruction. — The part of woman and of Household Economy Instruction (from the point of view of the simplification of household work).

2) *Household Economy Instruction in the Primary School.*

How and when should Household Economy Instruction be given to girls in the Primary School?

Is any form of special equipment necessary for this Instruction in the Schools in which it is provided?

If so, what should it be for town and country schools respectively?

3) *Household Economy Instruction as an integral formative element in the education and instruction of young girls of all classes.*

Should Household Economy Instruction be compulsory in Girls' Secondary Schools?

How and when should Household Economy Instruction be given in Girls' Secondary Schools?

Should each School be specially equipped for this Instruction?

What should be the equipment for Town and Country Schools respectively?

Household Economy Instruction for boys.

4) *Correlation of Household Economy Instruction with home education.*

How to make parents appreciate the value of this Instruction?

5) *Correlation with Technical Education.*

- 6) *Professional Training for Household Economy Teaching.*  
 a) How should courses for the scientific training of Teachers of Household Economy be organized?  
 b) The importance of establishing a definite Teaching Service for Household Economy.  
 c) The Pedagogy of Household Science. Should the instruction be individual, in classes with definite lessons or under the general direction of the Teacher.  
 d) What should be the equipment for Household Economy Instruction in professional Training Colleges?  
 e) The careers and prospects of Students in Household Economy Training Colleges?
- 7) *Inspection of Household Economy Teaching. -- Duties of the Inspectorate.*

#### Second Section.

#### TECHNICAL INSTRUCTION IN HOUSEHOLD SCIENCE.

- 8) *Rural Household Economy Schools.*  
 Ways and means of making Household Economy Instruction really effective in rural areas.

\* \* \*

The general notice of the Congress is accompanied by an extract from the *Bulletin of the Swiss Union of Technical and Household Economy Mistresses*, No. 4, Fribourg, April 15, 1921, setting out the resolutions of the Congresses at Fribourg (1908) and at Ghent (1913) and dealing with the main questions on the Agenda for the Paris Congress. This extract may be summarized as follows:

HOUSEHOLD ECONOMY INSTRUCTION IN GENERAL. — As regards the place of woman and of Household Economy Instruction (as making

for the simplification of household work) the School should lay stress on the main lines to be followed and on the detailed organization of the work, showing how the various small actions in each branch can be distinguished and arranged in orderly sequence.

*Household Economy Instruction in the Primary School.* — Pupils must have the requisite development of intelligence and adequate elementary instruction. Organization must be based on local requirements and the special needs of each group of pupils.

The pupil should be instructed in the keeping of household accounts ; in the country she should also be given a knowledge of the farm accounts which she will have to keep as mother of the family. At the same time she should have practice in making a ready reckoning of the net cost and nutritive value both of each dish and of each meal.

Household Economy work should not merely be grounded on knowledge derived from natural science courses, but practical household work should provide innumerable opportunities for the verification of scientific laws and incidental instruction in chemistry and physics.

Ideas on art should be suggested by the utensils, etc. in common use and the pupil taught to appreciate their beauty as well as the beauty of simple forms of ornament.

The equipment of a Household Economy School, whether in town or country, should as far as possible reproduce the home conditions of the majority of the pupils. The scheme of work and of the cookery course especially should be the main consideration. The school, even when in a town should give the pupil an idea of the economic and social importance of, the cultivation of flowers and vegetables, and for purposes of experiment and practical work there should be a garden attached.

*Household Economy Instruction as an integral formative element in the education and instruction of young girls of all classes.* -- Household Economy Instruction for persons above the School age should be given to girls who remain at school after the elementary school period (in secondary or higher schools, special and technical). It is a matter of importance that the subject should be included in the examinations which confer a certificate of capacity for Elementary School Teaching. It is desirable that it should be made a compulsory subject with such variations as the particular circumstances of each country may require.

*Correlation of Household Economy Instruction with home education.* — The home ought to assist the teaching by encouraging regular attendance and providing opportunities for the pupils to put into practice the lessons learnt at school. In order to popularize Household Economy Instruction Parents' meetings should be held and demonstration courses for working class women given. The Household Economy School should impart healthy ideas on the facts of life and inspire enthusiasm for simple tasks.

*Correlation with Technical Education.* — The geometric system (based on personal measurements) should be adopted in instruction in cutting out and dress-making.

*Professional Training for Household Economy Instruction.* — Instruction should be given only by a mistress trained in a special Training College. Admission to such a college should be confined to girls who have obtained the elementary School Teachers' certificate or its equivalent and the minimum duration of the course should be for a year. The course should include instruction in Science (physics, chemistry, natural history) limited to its application to household work and in so far as it tends to make the students discover the rationale of the various processes included in their work. Rudiments of medical knowledge (hygiene, physiology and practical medicine) should be taught simultaneously in connection with discussions on the chief bodily organs and their functions. The more general instruction should be given by the staff, certain branches, such as child nurture and hygiene (human and animal) being entrusted to specialists.

The following methods for providing the teachers with the means of improving their knowledge are suggested: conferences or study circles; repeater or special courses; technical libraries. Criticism lessons also serve a very useful purpose.

The instruction both theoretical and practical, should be in groups and at the end of the course an examination should be held. The housework should be carried out, entirely if possible, by the students in training with the help of children in the last two years of the elementary school, working in groups under the orders of the students responsible and the general direction of the Principal in charge of the Household Economy Instruction. All the housework of the school which has educative value (maintenance of cleanliness and order, orderly and tasteful arrangement of furniture, general control of the work and conduct of the children) should be entrusted to the students themselves and carried out by them under the strict and regular control of the teaching staff.

The Household Economy Teachers' Training College can be more or less agricultural in character according to the special needs of particular countries.

**TECHNICAL INSTRUCTION IN HOUSEHOLD ECONOMY.** — The Household Economy School can be expected to serve to some extent as a beneficial influence in connection with rural depopulation and rural problems in general by giving women a high conception of their function, both social and occupational, as heads of the farm household.

Continuation School work should meet the needs of a) young girls on leaving the Elementary School; b) wage-earning women such as domestic servants, factory and work-room hands, shop-girls, clerks, etc.

It is to be hoped that employers of labour will be willing to allow a Household Economy Class to be formed in their factories or workshops for the benefit of their young women workers or that at least they will grant full facilities to their young women workers and clerks to attend local classes.

Peripatetic courses should be given where it is not possible to have a permanent school.

**SCIENTIFIC QUESTIONS CONNECTED WITH HOUSEHOLD ECONOMY.** — Household Economy Schools can help in social betterment from the point

of view of Working Class Housing, Food, Infant Hygiene, Co-operative Purchase and Consumption, High Prices and Adulteration. The subjects of Instruction will include, rational feeding and vegetarian cookery ; the campaign against Alcoholism, Tuberculosis and Infant Mortality ; how to market ; social and charitable work.

Finally among resolutions of a general character is included one urging that in all countries where Household Economy Teaching is left to private initiative, there should be a federation of Committees, each preserving its own individuality, in order that the work and the benefits to be derived from it may enjoy the stimulus of concerted action.

## CROPS AND CULTIVATION

### AGRICULTURAL METEOROLOGY

- 5 - **Information Concerning the Amazon Region, Brazil.** — LE COINTE, P., in *Revista Commercial, Industrial e Agricola do Pará*, Year 10, No. 13, pp. 111-129, fig. 9. Belem (Pará), December 1920.

The immense basin of the Amazon, the typical region of *Hevea brasiliensis*, offers boundless sources of wealth to the planter and timber-merchant, but the adequate working of these vast forests depends upon two factors, a sufficient supply of labour and the skilled direction of experts in woodcraft. The colonisation of this territory is hindered by the climatic conditions, but their importance is often exaggerated. It must not be forgotten that the distribution of meteorological values differs considerably in the various sections of this vast region. Hence side by side with depopulated zones, where marsh fevers are rife, wide tracts of country are found which owing to the healthy climate are a pleasant dwelling-place even for the European settler.

The author gives an account of his study of the climate of the Amazon region, basing his remarks chiefly on data collected in the districts of Belem, Obidos and Manaos

TEMPERATURE OF THE AIR. — The thermometric observations naturally give very different results according to the localities where they have been made. It is however noticeable that, generally speaking owing to the slope of the Amazon basin towards the Atlantic coast, the East and North winds find their way unhindered into and sweep right through the valley, and the great evaporation they produce on coming into contact with the damp forest growth, largely tends to prevent any excessive rise in temperature ; on the lower Amazon, the average annual temperature is never above 28° C.

In the town of *Belem* (Pará), uninterrupted observations have been made at the Goeldi Museum for twelve and a half years ; similar meteorological work was done in 1897 at the Secretariat of Public Works and at the Lauro Sodré Institute ; the general average readings recorded (in centigrade degrees) were as follows : January, 25.9 — February, 25.3 — March, 25.9 — April, 25.9 — May, 26.1 — June, 26.3 — July, 26.4 — August, 26.3 — September, 26.6 — October, 26.8 — November, 26.8 — December, 26.4 — *annual average* 26.2.

The monthly means for 3 ½ years of observations in the town of *Obidos* (Pará), on the Amazon, about 900 km above Belem are as follows: January, 27.09. — February, 26.55 — March, 26.43 — April, 26.17 — May, 26.25 — June, 26.02 — July, 26.62 — August, 27.67 — September, 28.05 — October, 28.44 — November, 29.04 — December, 27.70 — *annual average* 27.17.

In the town of *Manaos* (Amazon) situated on the Rio Negro, a tributary of the Amazon 1574 km. above Belem, the thermometer readings are as follows: average annual temperature 26.8° C — maximum temperature (October 27, 1902) 37.5° C. — minimum temperature (April 28, 1902, 18.8° C — annual absolute deviation 18.7° C.

Thus, at any rate in the lower and middle valley, the weather is characterised by constant high temperatures with regular and slight variations. The variations, at Belem are in direct relation with the rainfall. In February which is the wettest month, the temperature is lowest, and November, the driest month, is also the hottest.

At Obidos and Manaos, the minimum temperature is registered in May-June, the thermometer falling through the influence of the "friagem", cold winds that rush down from the Andes. Here again however the greatest heat comes in November, the month of least rainfall.

As one leaves the river-banks and ascends the course of the tributaries, the heat decreases, and the difference between the day and the night temperature increases.

At 100 km. to the north of Obidos on the Ariraniba plateaux, at an altitude of 280 m., the heat is already tempered by the drier air and strong ventilation from the north-east. Further north again on ascending terrace by terrace, the great amphitheatre that rises perpendicularly from the river, the traveller finds a temperate climate in Brazilian Guiana, which with its fine natural pastures would offer every advantage to the colonist, were it not that the waterfalls interrupting the course of its rivers, and the total lack of roads, render all access to the country very difficult.

The upper part of the basin of the southern tributaries (Jurna, Purus, Madeira), is swept at certain times of the year (from March to June) by intermittent violent winds (southwest) coming from the Cordilleras which are still covered with snow. These winds are known as "Sur", or "Friagem", and produce a sudden fall in the temperature. According to the author, on the Madidi, a tributary of the river Beni (Upper Madeira), in Bolivia, the thermometer drops in a few hours from 38° C to 11° C. Owing to the sudden lowering of the temperature, the atmosphere becomes saturated with moisture and a thick fog obscures the sun and extends over the district. The "Friagem" wind arises on calm hot days, shortly after the sun has passed the meridian, and is preceded by a fall of the barometer (5 to 6 mm.). The wind blows for 3 to 8 days.

The effects of the Friagem can be felt though to a very limited extent as far as Ovidos and Manaos.

TEMPERATURE OF THE SOIL. — At Belem the soil temperature, at 1 metre below the surface, varies from 26° C. to 28.5° C. From observa-

tions made at the Lauro Sodré Institute (from 1904-1907), the annual average temperature is 27.45° C. At a depth of 30 cm. the average is 27.90° C.

**RAINFALL AND FOGS.** — The changes of temperature are not sufficiently marked to make it possible to divide the year into seasons. There are however two distinct periods, the rainy and the dry. The North-East Trade Winds passing over vast ocean tracts heated by the tropical sun, carry periodically into the basin of the Amazon enormous masses of water-vapour which ascend the valleys as far as the eastern ramparts of the Corderillas.

The sky is rarely clear, being usually greyish-blue and the horizon is veiled by thick fogs. The average nebulosity is 5.35 at Obidos, 6.3 at Manaos and 5.3 at Belem. In the latter town, it is 6.9 during the rainy season (January-April) and 3.6 during the dry (August to November).

At Belem, the so called dry period is only relatively dry for more or less rain falls throughout the year according to the seasons. The rains begin at the end of December, and attain their maximum from January to April; the winter, as the rainy season is called, finishes in August. The driest summer months are September, October and November.

All the country to the east of Gurupa, which includes the "furos" district, the great part of the "island" zone, the south and south east of Marajo and the right bank of the Pará as far as the coast, have the general climatic conditions of the Tocantin zone though slightly modified by the vicinity of the ocean.

From the observations made from 1894 to 1911, at the Museum, at Belem, the rainfall in that town is distributed as shown by Table I.

TABLE I. — *Rainfall Distribution at Belem from 1894 to 1911.*

January	296 mm	27 wet days
February	360 "	26 " "
March	388 "	28 " "
April	370 "	26 " "
May	261 "	24 " "
June	195 "	22 " "
July	166 "	19 " "
August	119 "	16 " "
September	87 "	16 " "
October	80 "	15 " "
November	64 "	13 " "
December	150 "	20 " "
Totals	2 486 mm.	252 wet days

The relative humidity of the air is always very high; the 10 years' average being: January, 92.3 — February, 93.08 — March, 92.5 — April, 91.5 — May, 89.1 — June 86.1 — July, 86.1 — August, 86.1 — September, 85.2 — October, 84.2 — November, 85 — December, 87.6 — *Annual average* 88.3.

TABLE II. — *Rainfall Distribution at Obidos.*

	Amount in mm.	Wet days	Relative humidity
January. . . . .	124.3	21.8	80.76
February . . . . .	173.2	20.2	81.25
March . . . . .	316.9	21.6	84.74
April . . . . .	225	23	85.34
May . . . . .	155.1	18.6	83.69
June . . . . .	93.8	12.6	79.33
July . . . . .	49.3	7	73.66
August . . . . .	14.4	4.5	69.26
September. . . . .	63	5.5	70.80
October . . . . .	67.5	5	65.00
November . . . . .	77	5.2	62.49
December. . . . .	113.3	12.7	78.77
<i>Totals . . . . .</i>	<b>1592.3</b>	<b>157.1</b>	<b>76.26</b>

At Macapá on the northern bank of the estuary of the Amazon, the rainy season, which lasts for 8 months is clearly marked off from the dry season lasting for 4 months during which almost absolute drought prevails.

The same division of the year is met with on ascending the lower course of the great river, but the rainy season is reduced to 6 months and the amount of rainfall is correspondingly diminished. Table II gives the results of the observations made at Obidos during 4 ½ years.

On the lower course of the Amazon, the North-east wind ("vento geral"), brings the dry weather and the west and the south-west wind ("vento de cima"), bring the rain.

At Manaus almost the same conditions are to be observed as at Obidos. The averages for five years are given in Table III.

Travelling from Manaus towards the interior of the basin the relative humidity is observed to increase, until the saturation point is reached, and condensation takes place owing to the countless streams, lakes and swamps that cover this region. At Porto Velho on the river Madeira, the rainfall already amounts to 2640 mm., distributed as follows: January, 373.8. — February, 338.8 — March, 330.2 — April, 255 — May, 139.2 — June, 52.8 — July, 17.8 — August, 34 — September, 142.2 — October, 240 — November, 328.1 — December, 386.8.

On ascending the course of the Purus, the climate becomes continually damper and the rainfall increases; the amount of water falling annually at Tefé is already double that falling at Obidos; at Pebas, the rainy season lasts nearly the whole year. From this point however the rainfall continues to diminish, at Iquitos (Peru), the average temperature is 4.8, the relative humidity 83, and the total rainfall 2840 mm.; August is the driest month. Finally Cordillera de los Andes, the Western boundary of the basin is reached; there the large masses of water vapour which pass up the great river valley from the Atlantic Ocean are condensed in the form of the rain that incessantly beats upon the eastern slopes of the mountain chain and the snows that cover its lofty summits. This condensation is so complete, that almost absolute dryness prevails on the other side of the crest on the Pacific slope.

*Other Meteorological Phenomena.* — In spite of the excessive humidity, fogs are somewhat rare owing to the constantly high temperatures; they are however occasionally to be seen in the early morning in April and May. Little dew falls on the deforested land of the lower reaches of the river, but heavy dews are common in the interior of the country. Violent hurricanes and sudden gusts of wind are of rare occurrence. The atmospheric pressure like the temperature is subject to slight and regular variations; it attains its maximum in the morning and diminishes progressively during the day.

TABLE III. — *Distribution of Rainfall at Manaus.*

	Amount in mm.	Wet days	Relative humidity
January . . . . .	240	22 7	82
February . . . . .	248	20	81
March . . . . .	290	19 6	83
April . . . . .	202	15 6	82
May . . . . .	135	14 6	82
June . . . . .	43	4	77
July . . . . .	89	4 6	76
August . . . . .	51	4 3	74
September . . . . .	38	7	73
October . . . . .	45	12 3	72
November . . . . .	30	10 3	71
December . . . . .	225	19 3	78
Totals	1 657	151 3	77 6

The degree to which the Amazon climate is healthy depends largely upon all the factors discussed above and varies considerably in different parts of the immense region. The climate is distinctly unhealthy in the interior, but continues to improve in the riverine zone of the middle and lower portion of the great river (1).

#### 6 - Influence of Climate on the Fixity of Hybrids from the Standpoint of the Segregation of Characters in the Second Generation. — See No. 26 of this Review

(1) On the other hand, the progressive draining of the interior (sertão) and systematic cultivation will gradually bring about the disappearance of the swamps and in consequence greatly increase the salubrity of the region. As Dr. Deodécio DE CAMPOS, Delegate of Brazil at the International Institute, has informed us, the district of Belem -- in the low-lying district of the estuary of the Para -- now enjoys a very healthy climate, owing to the drainage operations that have been carried out and to the energy of the special Sanitary Service (directed by Professor Osvaldo CRUZ), which has completely freed the town from mosquitoes. (*Ed.*)

7 - **Researches on the Specific Gravity of Certain Soil Constituents from the Point of View of the Fineness of the Soil Particles.** — NOLTE, O. (Landwirtschaftliche Versuchsstation zu Braunschweig), in *Internationale Mitteilungen zur Bodenkunde*, Vol. XI, Parts 3-4, pp. 117-118. Berlin, 1921

SOIL PHYSICS

In theory it might be expected that the finer a body is, the less should be its specific gravity and this has again been proved by the author as regards certain typical soil constituents. He determined, with the help of a pycnometer, at 17-19° C, the specific gravity of fractions separated by mechanical analysis, estimating their density when air-dried at 100° C, and calcined, as compared with the specific gravity of water at 4° C. By this means as regards the precipitated silicic acid and kaolin, perceptible differences were found between the specific gravity of the fraction that was precipitated in less than 24 hours, and the fraction deposited subsequently; these differences showed themselves at the 2nd and even the 1st decimal place. On the other hand, in determining the chemical composition of fractions of a stiff clay deposited in 24 hours and after this time had elapsed, it was found that not only some of the colloidal portion remained in suspension, but also that there were great differences in their composition; thus the silica fell from 56.45 to 53.2 and 53.1%; the alumina rose from 37.26 to 40.9 and 42.0%; and the sesquioxide of iron from 1.84 to 2.3 and 2.5%, the amount of lime, magnesium, and sodium varied; on the other hand, the potassium content increased considerably, from 0.24 to 0.8 and 1.2%; oxide of titanium was only present in the intermediate fraction. The variation of the specific gravity of the portions obtained by means of more fractional deposition is characteristic, as is seen from the following Table:

Specific Gravity	Fraction precipitated				
	Before 100 seconds	After 100 seconds	After 15 min	After 2 hours	After 24 hours
Expressed in relation to air dried material . . . . .	2.467	2.470	2.492	2.482	2.317
Expressed in relation to mat- erial dried at 100° C . . . .	2.026	2.615	2.640	2.638	2.497
Expressed in relation to calc- ined material . . . . .	3.317	3.115	3.017	3.048	3.008

This shows, that there is a considerable difference between the finer particles and the coarser ones, which do not vary perceptibly.

8 - **Effect of Temperature Upon the Absorbent Properties of Soils.** — STOQUER, in *Comptes rendus de l'Académie des Sciences*, Vol. 173, No. 17, pp. 731-733. Paris, October 24, 1921.

Agricultural soils experience great variations of temperature. In the neighbourhood of Paris the difference between the monthly averages of the same soil in July and January has been found to amount to 24.4° C

at the surface and to  $19.3^{\circ}\text{C}$  at a depth of 0.25 m. (FLAMMARION). DE GASPARIN found a difference of  $3^{\circ}\text{C}$  at Orange.

The author wished to ascertain whether such variations had any effect upon the soil's power of fixing certain fertilising substances. He selected 4 soils differing in composition and studied their capability of absorbing sulphate of ammonium at  $0^{\circ}\text{C}$ ,  $16^{\circ}\text{C}$ ,  $35^{\circ}\text{C}$  and  $55^{\circ}\text{C}$ .

The experiment was carried out as follows: an amount of soil equivalent in weight to 100 gm. of dry soil was introduced into a flask, together with a total volume of 250 cc. of a very diluted solution of ammonium sulphate. The flask, which was kept in a bath at a constant temperature, was well shaken at the beginning and was afterwards shaken every 15 minutes for 1 hour. In order to clarify the solution, the flasks were left for 3 hours in the bath at the same temperature. A portion of the clear liquid was decanted and the ammonium present determined by distillation in the presence of magnesium. From the result obtained, the amount of ammonium fixed by the soil is estimated.

The total results are given in a Table from the study of which the following conclusions can be drawn:

1) The absorbent power always increased with the concentration of the solutions. This confirms an already well-known fact.

2) Under the conditions of the experiment, the absorbent power was sometimes negative (that is to say, the soil gave up some of the ammonium to the solution), or even sank to zero (when the solution contained the same amount of ammonia as the given soils). This occurred, within the limits of the temperatures studied, in the case of the first three soils with a 0.02/1000 solution, and in the fourth (garden mould), with a 0.08/1000 solution.

3) All the soils gave up ammonium to the distilled water (as was to be expected), and the amount yielded increased as the temperatures rose.

4) The absorbent power of the soil, as regards sulphate of ammonium decreased when the temperature was raised.

5) At temperatures that easily occur in soils, some are able to yield up their ammonium to 0.02/1000 and stronger solutions. These soils are not very poor in ammonium, and may have received a dressing of ammoniacal fertilisers. In certain circumstances, the amount of ammonium removed from the soil (without even being converted into nitrate), by the percolating rain-water is perhaps larger than is generally supposed.

The opinion is gradually gaining ground that soil solutions, in spite of their low content in fertilising substances, exercise a great influence upon plant nutrition. These solutions, as is seen from what has already been said, are richest in ammonium at the warmest periods, which is just when plant growth is most active; hence we may suppose that some correlation exists between the two phenomena.

9 - **Relation between the Nitrogen Content of the Soil and the Yield of Indigo in India.** — See No. 50 of this Review.

10 - "Taungya" Cultivation in the Shan States, Burma, and Methods of Soil Treatment Recommended. — THOMPSTONE, E. (Deputy Director of Agriculture, Burma), in *The Agricultural Journal of India*, Vol. XVI, and Pt. 3, pp. 251-264, Pt. 4, p. 396-405. Calcutta, May-June 1921.

The "taungya" system of cultivation as practised in the Shan States, Burma, and elsewhere, has been the subject of official investigation for many years, chiefly on account of the enormous amount of damage done to forest areas and the heavy destructions of timber. The system includes the cutting down of the jungle growing on the hillside, lopping off any branches of the trees and heaping these up with the brushwood, etc. round the stumps and then firing the whole. This operation takes place during the dry weather (February to May). Subsequent cultivation depends upon the slope of the ground and often the use of a hoe is the only implement possible on the steep hillside.

After burning, the heaps are allowed to cool and if the crop grown is potatoes, the setts are planted in mounds from 1 to 3 setts in each; for other crops the heaps are spread by hand and the seed is sown broadcast. The principal crops grown in the Myelat are paddy and potatoes with an occasional crop of sesamum. Other crops grown are maize, ginger, ground-nuts, sweet potatoes, gourds, opium, cotton and several kinds of beans.

The land is cultivated from 1 to 3 years (rarely 4) and then allowed to lie fallow for a considerable period. The actual "taungya" process is varied somewhat according to locality, conditions of fuel supply, etc.

The cultivator often attributes the success of his "taungya" crop to the destruction by fire of insects and fungi, and his failure after 2 or 3 years, to the return of these pests. However, investigations have shown that the probable effect produced can be traced as follows: — The young crop first makes use of the ammonia directly produced by the heat and later of that produced by the increasing number of bacteria. This continues till the crop is harvested, after which the production of ammonia is lessened by its accumulation (which checks the activities of the bacteria) in the soil, and later by the drying of the soil which will eventually arrest the process and check the multiplication of both classes of micro-organisms for the period of the dry season. At the break of the second rains the soil bacteria still retain the upper hand, but before the season's crop has been harvested the destructive organisms are rapidly gaining ascendancy, and before the dry season again comes round, the increase is marked, at the expense of bacteria. Once the original state of equilibrium is fully established between the two classes of organisms, the effect of the burning will have disappeared and the soil will have returned to its previous natural state, which on account of its poverty in lime and organic matter will entail unprofitable crop production over very large areas.

The results of practical field experiments strongly support this theory, and the ultimate aim of all "taungya" investigations has been to bring land under permanent cultivation, to put a stop to this destructive method and thus to induce the people to settle down on holdings of reasonable size with consequent substantial benefit to the country.

Results obtained at Yawnghive and Hsumhsai (Burma) suggest a simple and practical solution of the problem and the author here describes in detail a few typical cases.

There are obviously two ready substitutes for the heat (1) now being so laboriously applied, viz. lime and organic manures, small dressings of either have given more productive results and seem to be more lasting in their power than an ordinary "taungya" burning. The following examples demonstrate this fact:— The average increase in wheat yield on land to which lime was applied at the rate of 6000 lb. per acre, amounted to 273 lb. per acre (120 %) on land that had been cultivated for one year without previous burning, and an increase of 3440 lb. per acre of maize is reported on old "taungya" land. Corresponding results were obtained with *Phaseolus lunatus*, *P. calcaratus*, *Cajanus indicus*, *Cicer arietinum*, *Polygonum Fagopyrum*, etc.

As regards organic manure, in every case so far tried, the benefit derived from unburnt manure proved to be greater than that brought about by burning an equal quantity of manure. The following figures show also the advantage of planting potatoes in drills.

	Yield of tubers lb. per acre	Yield of grain lb. per acre
1919-20. In drills . . . Manure unburnt	9620	1200
" " . . . Manure burnt . .	6960	900
" " . . . No manure . . .	2800	nil
Hill method. . Manure unburnt	4000	—
" " . . . Manure burnt . .	3540	—

These results were obtained without the aid of lime, but a combination of lime and manure gave also very striking results. (Lime had been applied 2 years previously, 5000 lb. per acre).

	Yield of potato tubers lb. per acre	Yield of grain lb. per acre
Manure and lime . . . . .	8780	1960
" (without lime) . . . . .	6160	520

Some of the older plots that have so far received neither lime nor manure have however still maintained their yields by good cultivation and rotations, and leguminous crops have been grown with success.

The author considers that liming, manuring and good cultivation, combined with a proper system of rotation can make continuous cultivation

(1) See R Jan 1913, No. 14, and R. June 1913, No 616. (Ed.)

much more profitable than the present methods of shifting from place to place. The natural advantages for agriculture and the evident future possibilities for the Shan States make the need for experimentation extremely important.

MANURES  
AND  
MANURING

I. — Experiments to determine the liming effects of high calcium and high magnesium limestones, as well as of their burned and hydrated products.

The tests were carried out on permanent experiment plots of silt loam which were ploughed in 1893, and cropped with maize until 1899, after which various crops were grown till 1909, when the present experiments were begun. No lime, manure or fertiliser had been previously used. The first application of lime was made in 1909-1910, the amount used being sufficient to neutralise the same quantity of acid. The second and third applications of lime were made in 1914 and 1916. The latter completed the neutralisation of the soil acidity when, judging from the influence of the carbonated water, the speed of reaction of the limes would decrease in the following order: Magnesian hydrate, calcic hydrate, calcic limestone, magnesian limestone. From 1909 to 1921, the crops were mixed; hay, maize, potatoes, etc. No farm manures were used, but chemical fertilisers were usually applied so liberally that the liming materials were expected to act as neutralisers only and not as sources of plant food.

Beginning in 1917 the proportion of magnesium to calcium was increased by using in the mixture low-grade sulphate of potash and double superphosphate.

In 1920 the ratio of magnesium oxide to calcium oxide extracted from the soil by carbonated water was about  $\frac{1}{7}$  from the plots receiving the calcic limes;  $\frac{1}{1.7}$  from those receiving the magnesian limes, and  $\frac{1}{2.2}$  from the unlimed plot. The yields were equally satisfactory whether the ratio was  $\frac{1}{7}$  or  $\frac{1}{1.7}$ . In 1917 the ratio of magnesium oxide to calcium oxide in dried endive was respectively  $\frac{1}{1.1}$  to  $\frac{1}{1.5}$  with the plots that had received magnesian hydrate and limestone; from  $\frac{1}{2.2}$  to  $\frac{1}{3}$  in the case of the plots given calcic hydrate and limestone, and  $\frac{1}{2.8}$  in the control plot without lime.

The humus content and loss on ignition indicate slightly less organic matter in the soil to which the hydrates instead of the limestones had been added. It can scarcely be concluded with certainty that the different limes have been accompanied by a change in the nitrogen content of the limed soil as compared with that of the unlimed soil, although the percentage of nitrogen is slightly higher where magnesian limestone was used. The unlimed plot was decidedly acid as compared with the limed plots, but it was the only one from which aluminium was extractable by certain normal salt solutions, and by carbonated water.

Certain sensitive crops have been greatly benefited by the liming; the beet yield for instance was frequently increased sixfold. Even these crops did not however react to the liming in such a way as to warrant generalisations concerning the specific effects of the different kinds of lime. Practically like effects may be generally expected whichever of the four forms is used, from an application having a given neutralising equivalent, that is, based upon the percentage of magnesium oxide multiplied by 1.4, plus the percentage of calcium oxide, provided that the limestones are sufficiently fine to pass through an 80-mesh sieve, and that the hydrates are used with the ordinary precautions.

II. — Lime is the key to soil fertility building, since the economic use of both manure and commercial fertilisers is dependent upon the lime supply of the soil.

The author tested the value of several lime-bearing materials in 3 different parts of the State. In one case, he compared the effect of : 1) burnt lime ; 2) burnt oyster-shell ; 3) shell marl ; 4) pulverised raw shell. The shell marl gave the highest yield of wheat and hay while the pulverised shell produced almost as much wheat and hay and a larger amount of maize. It should be mentioned that the marl contained nearly 3 % of potash which may account for its superiority.

In another experiment, a comparison was made between the effects of pulverised raw oyster shell, burnt oyster shell, pulverised raw limestone and burnt limestone ; the total average increase on the two plots during seven years as compared with the control plot, expressed in dollars per acre was 78.43 for the pulverised oyster shell, 73.85 for the burnt oyster-shell, 77.60 for the pulverised raw limestone, and 77.05 for the burnt limestone ; thus the differences between the effects of the various forms of lime used are negligible. In another experiment with lucerne, it was found, that raw pulverised limestone gave better results than raw oyster-shell lime, burnt limestone and hydrated lime.

In conclusion, the author advises agriculturists to determine whether their soils need lime and the amount required.

III. — The practice of liming has been sometimes encouraged and at other times discountenanced, which shows that if lime must be used it should be applied in moderation. The author described the experiments made of recent years by the Chemical Division of the Organisation of the Experiment Farms of East Canada. These have proved that in many

places, the yield has been increased by liming, especially in the case of clovers which form the basis of profitable agriculture.

In one experiment on clayey-sand the application of 672 kg. of potassic fertiliser per hectare which supplied 22.4 kg. of nitrogen, 44.8 of phosphoric acid, and 56 kg. of potash, and was spread before oats were planted, produced in 1914, 51.57 hectolitres of grain per hectare. Another plot treated in the same manner, but to which 2240 kg. of ground limestone was applied, produced 59.58 hectolitres per hectare (or 8 hectolitres more than the first plot). The second year of the rotation, the unlimed plot bore 55.5 quintals of clover and timothy-grass hay, whereas the limed plot yielded 83.8 quintals or 28.3 quintals more.

In another experiment two series of parallel plots on soil similar to the preceding, were dressed at the beginning of each rotation in the autumn with 50.2 quintals of ground limestone, and in the following spring each of the series was given a different manure. In 1919, two three-year rotations of potatoes, cereals and clover gave the final results set forth in the following Table.

Leaving out of account the evident effect of the dung, these data show that the lime stimulated the action of the fertilisers and their residues in each three-year rotation. The effect of ground limestone is especially noticeable in the case of grasses particularly where basic slag was applied.

*Average Yield per Hectare.*

1st Rotation (1914-16)	Potatoes 1914 hectolitres	Oats 1915		Hay 1916 quintals
		Grain	Straw	
		hectolitres	quintals	
Control . . . . .	50.31	27.36	18.1	8.06
Limestone alone . . . .	60.84	29.52	18.7	12.43
Chemical fertilisers alone . .	76.02	28.53	20.4	7.39
Fertilisers and limestone . .	86.04	34.56	24.6	16.73
IInd Rotation (1917-19)	Potatoes 1917 hectolitres	Wheat 1918		Hay 1919 quintals
		Grain	Straw	
		hectolitres	quintals	
Dung alone . . . . .	226.62	17.55	22.2	29.57
Dung and limestone . . . .	282.06	26.82	25.3	45.81
Dung and chemical fertiliser	263.16	20.93	22.4	33.01
Dung, fertiliser and limestone	296.37	27.18	29.4	55.17

In an experiment on sandy soil, where a comparison was made between unlimed plots and others to which 5 tons of limestone per hectare had been applied, the average yield of seed per hectare was for 3 varieties of barley 10.58 and 43.68 respectively — for 5 varieties of oats, 100.12 and 113.57 — for 4 varieties of wheat, 36.12 and 46.04 — for 4 varieties of peas, 39.14 and 79.30.

In Canada, some of the commonest calcareous substances are marl,

or shell-marl, with a lime content varying from 30 to 90 %. The author advises the application of from 5 to 12.5 tons of dry marl for light and clay-sandy soils, and of 25 to 75 tons for heavy clays. The land should be ploughed and harrowed both in the spring and autumn. If marl is to be obtained, there is no need to get ground limestone or lime, for marl is cheap, improves the soil greatly and increases the yield.

This Bulletin concludes with a series of analyses of the calcareous substances suitable for agricultural use that are to be procured in the different provinces of Canada.

**12 - The Present Condition of the Superphosphate Industry in Japan.** — ISHIKAWA I., in *Kōgyō-Kuagata Zasshi* Vol. XXIV, No. 7, pp. 700-717, figs. 5. Tokyo, July 1921.

In Japan, the greater part of the people are engaged in farming, and the capital invested in agriculture is three or four times higher than in the manufacturing industries. The area of land cultivated for 2 000 years is as follows :

Rice-fields . . . . .	3 010 000 chobu
Under other crops . . . . .	3 070 000 "

1 chobu = about 2.45 acres).

The rate of increase in population amounts annually to 1.0 per cent. while that of rice-fields, and other fields under cultivation is only 0.4 per cent. in each case. Therefore, if Japan does not make efforts to intensify production by using chemical fertilizers, the food problem will become serious.

The fertilizers used are bean cake, rape cake, cotton-seed cake, pressed herring, pressed sardine, bone meal, Chili nitrate, ammonia sulphate, superphosphate and mixed fertilizers. In 1919, the total cost of these fertilizers (with the exception of Chili nitrate) was estimated at 240 000 000 yen (1 yen = about 2 shillings at par), of which 10 % was superphosphate and 60 % bean cake.

The present condition of the superphosphate manufacturing industry is as follows :

Number of companies . . . . .	15
Number of factories . . . . .	28
Productive capacity . . . . .	25 000 000 yen
Nominal capital . . . . .	72 000 000 "
Capital paid . . . . .	53 000 000 "
Current capital . . . . .	111 000 000 "
Permanent investment account . . . . .	28 000 000 "

The number of sulphuric acid plants, which are closely connected with the superphosphate industry, is 53 and most of them are in the Tokio and Osaka districts.

In 1888 the first artificial fertilizer company in Japan was established. Since the China-Japanese and Russo-Japanese wars, as a result of the prosperous conditions of the market, new companies were established. When trade became dull, amalgamation took place, so that the present companies rest on a stable basis and are reliable.

The demand for mineral phosphate is 300 000 tons yearly, while the home production is chiefly from Rasa Island ; but its maximum production amounting to 110 000 tons per annum only, Japan must continue to import the raw material. Angaur Island has lately come into the possession of Japan and it will somewhat neutralize this disadvantage ; its reserve, however, is said to be only 2 000 000 or 3 000 000 tons. Probably more mineral phosphate will be supplied from the province of Kiangsu (China), and from Hirata Island, south of Hainan Island.

As to sulphuric acid, there are 124 lead chamber and tower system plants and 8 plants employing the contact process. The total capacity for production is estimated at 1 150 000 tons of 50° B $\acute{e}$ . acid per annum, the actual amount being 900 000—950 000 tons, 500 000—550 000 tons of which are used to produce superphosphate.

In Japan, superphosphate is mainly packed in straw bags, even though a small amount of burlap bags is used. The straw bags are mostly made by hand as farmers' by-products and the old bags are re-used by them for many purposes. Therefore packing by machine is not, for the time being, considered desirable. The present production of superphosphate amounts to 15 000 000 bags (1 bag contains about 83.3 lbs.) per annum, and if the time comes when more superphosphate is used for every area unit, e. g., 10 bags per 1 chobu, 30 000 000 bags will be required in Japan. Moreover, China is thickly populated and does not at present use any artificial fertilizer (1). When it does come into use in China large quantities can be supplied from Japan. Consequently there are limitless prospects for the superphosphate industry in Japan.

13 - **Relation of Organic Matter and the Feeding Power of Plants to the Utilisation of Rock Phosphate.** — BAUER, F. C., (Agricultural Experiment Station, University of Wisconsin), in *Soil Science*, Vol. XII, No. 1, pp. 21-39, tables 9, bibliography of 45 works. Baltimore, M. D., July 1921

The processes accompanying the decomposition and the feeding power of plants are undoubtedly important factors in the utilisation of rock phosphate. Experiments were planned in which common forms of organic matter were used with rock phosphate and in some cases provision was made for the removal of the soluble phosphorus and calcium in order more nearly to imitate field conditions in this respect. The soil medium consisted of either sand or soil, the former contained no soluble phosphorus. Experiments were made as follows : a) rock phosphate mixed with several forms of organic matter in sandy soil with no provision for the removal of phosphorus as it became soluble ; b) in similar mixtures provision was made by leaching and c) by upward moving capillary water, both for the removal of phosphorus as it became soluble ; d) study of the solvent effect of organic matter extracts with and without carbon dioxide on rock phosphate ; e) pot culture experiments, also made to ascertain this effect and to test the feeding powers of plants in relation to the utilisation of rock phosphate and felspar. The results may be summarised as follows :—

(1) See R. Sept. 1920, No. 880. (Ed.)

1) Experiments (a) (b) (c) and (d) failed to show a solvent effect of the decaying matter on rock phosphate, and in confirmation of results obtained by other investigators there was evidently a gradual decrease in the amount of soluble phosphate. The failure of the experiments to show an increase in the availability of rock phosphate was probably due to the fact that when organic matter such as was used (in this case, finely pulverised air dry buckwheat hay, sweet clover hay, alfalfa hay, soybean hay, mammoth clover hay, maize stalks, oat straw and chopped green buckwheat and sweet clover) decomposes, sufficient bases are liberated along with the acids that are formed, to neutralise the acids and prevent their action on rock phosphate. When mixtures of rock phosphate and organic matter are applied to soils, the conditions are different because of the capacity of soils to take up basic material, especially if they are acid.

In some cases mixtures of organic matter and rock phosphate applied in pot cultures produced increase in growth of maize over that produced by either the organic matter or rock phosphate when used alone. The phosphorus in the organic matter was readily available to growing maize. The organic matter furnished phosphorus to the seedling and thereby promoted growth which may have enabled the plant to feed more strongly on the rock phosphate or the rock phosphate may have been made more available by the chemical and biological processes accompanying the decay of the organic matter.

A study of the growth of 15 different plants on rock phosphate in sand cultures showed a wide variation in the amount of dry matter produced. The crops tested were red clover, sweet clover, wheat, oats, maize, timothy, soy beans, rape, alfalfa, rye, buckwheat, red top, red sorrel, mammoth clover and alsike clover. Tables show the average yields of dry-matter of the tops, roots and plants as a whole, the proportion of roots to the whole plant when grown with rock phosphate, and the percentage growth made with rock phosphate compared with that made with acid phosphate are recorded; also the phosphorus and calcium content of plant tops and acidity of leaves, stems, and roots of plants grown with acid cultures with no potash, soluble potash and felspar potash.

Results show that there was quite a wide variation in the growth of the different plants with rock phosphate used at the rate commonly advised for field practice. Sweet clover and red sorrel produced the largest proportionate increases of dry matter and red clover the smallest. The increases of the former were about  $3\frac{1}{2}$  times greater than the latter. Sweet clover possesses remarkable feeding powers relative to rock phosphate and felspar and is well suited to rotations for their utilisation. With the exception of sweet clover which gave a slight increase, all the plants analysed showed somewhat distinct decreases in the percentage content of phosphorus when grown on rock phosphate as compared with acid phosphate. In general, neither the percentage content, nor the total amount of phosphorus in the plant tops was related to the amount of plant growth made with rock phosphate.

The acidity values of the juice of the leaves, stems and roots varied considerably with the different plants. In general the juices were more acid when grown with acid phosphate than with rock phosphate.

The possibility of growing crops of high feeding power to supply organic matter and available phosphorus in rotation with crops of low feeding power is a question of considerable practical importance in the utilisation of rock phosphate.

- 14 - **The Effect of Basic Slag upon Grassland and the Subsequent Crops.** — OLDERSHAW, A. W. (Agricultural Organiser for East Suffolk), in the *Journal of Agricultural Science*, Vol. XI, Pt. 3, pp. 288-292. Cambridge, July 1921.

Two plots of grassland, each  $1\frac{3}{4}$  acres in extent, on a poor type of chalky boulder clay, were fenced off with wire netting; one was reserved for control purposes, and the other received a dressing of 10 cwt. per acre of basic slag, and a second dressing of a similar nature 8 years later. After 12 years of regular sheep grazing, on analysis of the first and second 9 inches of soil, the basic slag plot was found to contain 500 lb. of nitrogen per acre more than the unmanured plot.

The following year the plots were mown, ploughed up, and drained and sown with legumes and wheat successively, with dressings of superphosphate and sulphate of ammonia. The turf on the "slag" plot was very thick, and the yield was fairly high probably due to the thick growth of wild white clover. The increase in nitrogen as compared with the unmanured plot is only about 10%, whilst the increase in crop is much larger. It appears likely that the nitrogen assimilated being of more recent origin, would be more easily available to plants than the original nitrogen reserves of the soil. It is likely also that the extra plant residues left on the slagged plot, have a considerable influence on the mechanical condition of the soil and on its humus content. It is well-known that the presence of phosphate in heavy soil causes increased root development, but whether this applies also to slagged plots and the actual fate of the phosphates in this case, are points which still require investigation.

- 15 - **Results of Manuring with Superphosphate on the Yield and Quality of Indigo in India.** — See No. 50, of this *Review*.
- 16 - **Effect of Phosphate Fertilisers in Conjunction with Green Manures, upon Spring Cereals in India.** — See No. 50 of this *Review*.
- 17 - **Availability of Organic Nitrogenous Compounds.** — ROBINSON, C. S., WINTER, O. B., and MILLER, E. J. (Michigan Agricultural Experiment Station, East Lansing, Michigan), in *The Journal of Industrial and Engineering Chemistry*, Vol. XIII, No. 10, pp. 933-936, diagr. 1, New York, Oct. 1, 1921.

Several years ago investigations were started with the following objects: a) to ascertain the relation between the chemical constitution of organic nitrogenous substances and the availability of their nitrogen for plant nutrition; b) either to devise a new method or to improve the existing methods for measuring this availability. Both these questions are of importance because of the growing tendency to utilise all sorts of organic nitrogenous substances as fertilisers.

Amongst the various methods put forward for the determination of the availability of nitrogen as regards the said substances, two only, both of them developed rather empirically, have shown themselves of comparative value; *viz.* the alkaline permanganate and the neutral methods. In the present investigation the authors made determinations, employing the alkaline permanganate treatment, of the active insoluble nitrogen in a number of amino-acids and acid amides, typical organic compounds of known constitution in which the nitrogen was combined in several ways. After this, further investigations were made in a similar way, on the well-known proteins or substances containing them. Finally analyses were made of samples of commercial nitrogenous fertilisers employing the same method and the nitrogen partition method of VAN SLAYKE. Data relative to these determinations are given as follows:

*Per cent of Total Nitrogen of Fertilisers in Various Forms.*

	Total nitrogen	Soluble nitrogen (ammoniacal and nitric) + active insoluble	Amide nitrogen	Amino nitrogen	Amide + amino nitrogen
Peat (dried) . . . . .	2.76 %	40.21 %	20.65 %	39.14 %	59.79 %
Peat (wet) . . . . .	3.49	42.40	13.46	39.53	52.99
Pulverised sheep manure . . . . .	2.34	28.20	14.53	41.8	56.41
Hay and silage . . . . .	3.10	16.71	6.13	42.22	48.35
Fruit and vegetables . . . . .	3.74	43.85	5.09	49.20	54.29
Bone meal . . . . .	2.48	46.43	4.84	49.20	54.04
Animal tankage . . . . .	4.40	56.94	7.95	54.31	62.26
Pure bone meal . . . . .	3.12	62.81	8.01	55.76	63.77
Castor bean cake . . . . .	4.78	48.96	11.09	55.85	66.94
Cotton seed meal . . . . .	6.73	50.51	10.33	58.09	68.42
Bone . . . . .	3.05	67.21	5.24	60.98	66.22
Glue hair . . . . .	8.19	64.55	5.89	66.77	72.66
Beef scraps . . . . .	8.72	74.54	5.96	68.11	74.07
Hair waste . . . . .	14.27	70.85	9.52	70.00	79.52
Dried blood . . . . .	14.01	71.31	6.56	75.23	81.79
Mixed chrome uppers . . . . .	9.88	51.22	4.76	60.32	65.08

Assuming that the ammonifying as distinguished from the aminifying or hydrolysing power of the alkaline permanganate solution is comparable with the action of soil agents, all amino nitrogen and a portion of the nitrogen present as acid amides may be said to be included. There is also another class of compounds termed the potentially available class, which may be converted into the former class. This includes a portion of the acid amides, the peptides which can be hydrolysed to amino acids, and primary and secondary amides. The peptides probably constitute the great bulk of this class so far as ordinary fertiliser materials are concerned. This is the uncertain quantity in evaluating any material from the fertiliser standpoint. In some cases transformation into the available class is

so easy and complete that there can be no practical distinction between the two. In other cases however this process is so slow that the unavailable class is approached. Fundamentally, the problem of the determination of the availability of organic nitrogen compounds is the possibility of a proper estimation of the rate of ammonification of the members of this class. Up to the present the permanganate methods have proved the most satisfactory and the authors will publish later the results of their further studies.

**18 - The Influence of Certain Fertiliser Salts on the Growth and Nitrogen Content of Some Legumes.** — MAC TAGGART, A. (Cornell University), in *Soil Science*, Vol. XI, No. 6, pp. 435-454, figs. 2, bibliography of 61 works. Baltimore, M. D., June 1921.

It has been fully demonstrated that calcium plays an important part in the soil in the symbiotic assimilation of nitrogen by legumes, but the activity of certain other fertilising elements has not been so fully shown. For this reason the author after a bibliographical survey of the literature on this subject, gives the results of a series of experiments made with 36 boxes filled with a soil mixture consisting largely of clean sand and about  $\frac{1}{2}$  of sandy loam with slightly more than 0.5 % of calcium carbonate added to each box. The moisture content of the soil was maintained throughout at 10 % (on the dry-soil basis). Half of the boxes were filled with alfalfa and half with peas. The boxes were divided into 9 series of 4 and treated as follows: 1) control; 2) nitrogen (dried blood); 3) phosphorus (disodium phosphate); 4) potassium (muriate of potash); 5) sulphur (gypsum); 6) nitrogen, phosphorus, potash and sulphur in above forms; 7) nitrogen, phosphorus, and potash *idem*; 8) nitrogen, potash and sulphur; *idem*; 9) phosphorus, potash and sulphur, *idem*. Previous to sowing, all the boxes were inoculated with sand cultures. Following the crop of field peas, soy beans were sown, after suitable inoculation of the soil, application of calcium carbonate and fertiliser.

Of all the fertiliser elements applied, the phosphorus showed the most marked effect. Alone, it distinctly increased the dry matter and total nitrogen, and to a lesser extent the percentage of nitrogen in all 3 legumes; the order of average influence on the crop being: field peas, soybeans and alfalfa.

In combination with nitrogen, potassium, and sulphur, phosphorus markedly increased the dry matter and total nitrogen in peas, soybeans and alfalfa. However, it increased on the contrary the percentage of nitrogen in soybeans and alfalfa only slightly, and decreased the percentage in the case of peas.

Nitrogen as a single element can hardly be said to benefit the plants with respect to yields of either dry matter or nitrogen, except perhaps in the case of field peas. In combination with phosphorus, potassium and sulphur, nitrogen did not produce any lasting effect where it was employed alone; in fact, there was perhaps less response. It may be concluded also that nitrogen in combined form does not hinder nitrogen assimilation by legumes. Potassium used alone caused an increase in the total nitro-

gen and dry matter in field peas and alfalfa in the order named, but a decrease with respect to these factors in soybeans. Only in the percentage of nitrogen did potassium show an increase common to all 3 crops, in the order named above. Sulphur in the form of gypsum used alone or with other fertilisers somewhat increased the growth and nitrogen content of alfalfa, but does not appear to have had any effect on field peas and soybeans.

Taking into consideration the influence of the fertilisers employed for nitrification purposes or rather to assist in the nitrogen accumulation in the soil, the most marked effect generally was produced when phosphorus was applied, which resulted in the distinct development of the crops. Nitrogen applied alone increased soil nitrification after the harvesting of all three crops, particularly after alfalfa, but when applied in combination with other fertilising substances, it did not have this effect. Potassium, in the form of muriate of potash, apparently slightly inhibited nitrate-nitrogen accumulation; the sulphur, in the form of gypsum, increased nitrification subsequently in the soil. In general, there appeared to be a tendency toward correlation between the dry matter produced and the subsequent soil nitrification, due probably partly to the greater root system associated with increase in top growth, and hence to greater amounts of decayed roots, favourable to nitrification.

19 - **Carbonication of Plants By Combustion Gases.** - RIEDEL, F, in *Chemiker Zeitung*, Year XLV, No 104, pp 829 830 Cothen, August 30, 1921.

After having disposed of the various objections raised in connection with the practical installation of plant for the carbonisation of crops in the open field by means of combustion gases, especially those from siderurgical works (1) the author gives figures showing the economic returns from the process. He calculates that for the carbonication of one hectare of land, 500 m. of cement pipes with a diameter of 10 cm. are required; the distance between the pipes being 25 m. The price of the pipes in March 1921, was 7.5 marks per metre; counting transport and laying, the cost would work out at 12 marks the metre which would make 6000 marks per hectare; by adding a similar sum for the cost of the chief gas pipe and various expenses, the total amount would be 12 000 marks per hectare or 1.2 marks per sq. metre.

Calculating the working expenses per square metre the following figures are obtained;

	Marks
20 % depreciation and interest . . . . .	0 24
Cost of extra mineral fertiliser required . . . . .	0 12
Repairs . . . . .	0.08
Cost of extra labour necessitated by heavier crop . . . . .	0 10
Marks . . . . .	0.54

(1) See R. June 1920, No 626. (Ed)

If as a result of the carbonication, the potato crop is doubled; that is to say if it rises from 1.75 kg. to 3.50 kg., the net profit in the case of potatoes fetching 0.60 marks the kg., will amount to 0.51 marks per square metre or 42 %, and if early potatoes are grown, the profit is even higher. The prices quoted above are for installations that can use the discharge of gas motors which finds its way to the soil of its own accord; should ventilators for the expulsion of the gas be needed, this would mean an extra expense of some pfennige, but in any case there would be a good margin of profit.

As regards the larger water requirements of crops subjected to carbonication the author states, that the greater development in length of the plants' root systems enables them to make better use of the reserves of water in the soil. It may however be the case that in years of drought the full-benefit of carbonication can only be obtained by the application of carbon dioxide.

20 - **A Systematic Catalogue of the Plants Cultivated in Spain (Species and Varieties) and of the Principal Species of Trees.** - DANTIN CERCEDA J., *Catálogo metódico de las plantas cultivadas (especies y variedades) en España y de las principales especies arbóreas; Servicio de publicaciones agrícolas de Ministerio de Fomento*, pp. 62, figs. 22. Madrid, 1920.

AGRICULTURAL  
BOTANY,  
CHEMISTRY  
AND  
PHYSIOLOGY  
OF PLANTS

With this work of enumeration and identification which extends as far as possible even to varieties, the author begins his phytographical study of the plants cultivated in Spain. He does not pretend to have made a complete list, although many of the popular names he gives are recorded for the first time. In this catalogue, there are 422 species with their botanical names and the popular names by which they are known in the different Provinces of Spain. Then follows a table of 1000 popular names, and a bibliography of the 13 works most frequently consulted.

21 - **"Arroz brabo", Wild Rice in the Interior of Brazil.** - A Lavoura, year XXV, Nos. 8-9, pp. 219. Rio de Janeiro, September 1921.

In the State of Goyaz and in the inundation zone of the Araguaya, there are large quantities of a wild cereal much resembling rice, and known in the country by the name of "arroz brabo" (wild rice).

This plant only differs from common rice in having looser panicles and more brittle seeds.

In the neighbourhood of the river Jaoahé, "Arroz brabo" is used with much success in fattening stock.

22 - **Composition of Californian Citrus Fruits.** - CHACE, E. M. (Chemist in Charge), WILSON, C. S. and CHURCH, C. G. (Assistant Chemists, Laboratory of Fruit and Vegetable Chemistry), in *United States Department of Agriculture, Bulletin No. 933. Contribution from the Bureau of Chemistry*, pp. 1-18, figs. 4, bibliography of 5 works. Washington, Oct. 15, 1921.

From 1887, when 12 cartloads of citrus fruits were exported from California, until 1919-20, when 12 000 were exported, the cultivation of Californian fruits has been very widely extended. The varieties grown to the largest extent at present owing to their suitability to Californian conditions, are "Eureka", native of California raised from Si-

cilian citrons, and the "Lisbona", widely spread and imported directly from Australia. The authors have analysed the fruits of these two varieties and also of a third, viz. "Villa Franca", at the present time not grown. It is considered advisable that the grower should be kept acquainted with the data relative to the composition of the fruits no less than the manufacturing establishments directly connected with the products, such as oils and citric acid.

The results obtained indicate the comparatively negligible differences existing between the various characters of the varieties studied. The most outstanding are those with reference to the specific weight of the fruits; the Eureka seems to stand at the top and the two others were practically identical. As regards the essential oil content, the var. "Villa Franca" showed the highest percentage, whilst "Eureka" gave a somewhat lower percentage. Although no difference was noticed in the citric acid content, there was a marked difference in the sugar percentage between the Eureka and "Lisbona" varieties.

Acidity attains its maximum at the beginning of autumn; the maximum specific weight is reached towards midsummer, and the minimum during winter. The minimum essential oil content was found to be at the end of winter and in the spring, and the maximum in the autumn.

No correlation was observed between the colour of the bark, its thickness and the composition of the fruits, but the specific weight and the acid content became less with the thickening of the bark. No difference was observed between fruits obtained on the sea coast and those from inland.

23 - **A Study of Nitrogen and Root Space as Factors Limiting the Yield of Maize in Egypt.** — PRESCOTT, J. A., in *Sultanic Agricultural Society, Technical Section, Bulletin* No. 4, pp. 1-14, figs. 6 Cairo, 1920

The response of the maize crop to nitrate of soda has been shown as the result of field experiments conducted by the Sultanic Agricultural Society at Bahtim, to follow very closely the mathematical expression of MITSCHERLICH relating to the Law of the Limiting Factor (*Landw. Jahrb.* XXXVIII, 1909, p. 537; *Landw. Versuchs. Stat.*, LXXV, 1911, p. 231; LXXVIII, 1912, p. 127).

The dressing of nitrate of soda usually recommended in Egyptian farming is 150 kg. per feddan (1 feddan = 1.038 acre), but 200 kg. is frequently employed as a standard of comparison. In this experiment it was found that up to 300 kg. there was a steady increase in yield of crop, but if 400 kg. was applied, there was a smaller yield. Whether this diminution is due to the harmful effects of excess of nitrogen or of excess of sodium salts remains yet to be ascertained and the author proposes the repetition of the experiment, using ammonium nitrate instead of sodium nitrate.

It is frequently the case that the use of large quantities of nitrogenous manures retards the maturation of the crop; in the Bahtim experiments, however, no retardation has been observed.

The author includes data relative to harvest, effect of increasing dressing of sodium nitrate, etc.

*Root Space as the Limiting Factor.* — The spacings adopted varied from 25 cm. up to 95 cm. The original plots were each  $\frac{1}{10}$  feddan and were subsequently divided into two parts, the northern half receiving nitrate of soda at the rate of 150 kg. per feddan and the southern half being left unmanured :

In both the manured and unmanured series the mathematical expression of MITSCHERLICH can be applied with fair agreement.

The yield per feddan, according to the given curves, can be related to the number of plants per feddan, giving a maximum yield at the spacing of about 16 000 plants per feddan (nitrate series) and of 10 000 plants per feddan (unmanured series). It is significant that the local method of planting gives an intensity of about 12 000. However, within fairly wide limits, the yield does not appear to vary very much and it seems probable that the maximum crop would be between 12 000 and 20 000 in the nitrate series and between 8 000 and 14 000 in the unmanured series.

During the growth of the plant, weekly observations were made on the heights of the unmanured plants, the measurements being made to the tip of the longest leaf and later to the end of the tassel; curves are here given for the recorded heights. The plants in all the spacings grew together for the first 15 days after which there was a successive breaking away; it is thus possible to trace the course of the lateral root development and interference during the course of the season. The following data indicate this development during the growth period (diameter in cm.) for 5 successive fortnightly periods, *viz.* 25, 35, 45, 65, 85.

The author includes data relative to harvest as a result of sodium nitrate treatment and also for the spacing experiments, and curves, etc. showing the effects produced in every case.

24 — **Observations on the Growth of Maize in Egypt.** — PRISCOTT, J. A., in *Sultanic Agricultural Society, Technical Section, Bulletin No 7*, pp 1-25, figs. 10, tables 11, Cairo, 1921

During the seasons 1918 and 1919 observations were made in 3 different ways on the growth of maize.

I. AUTOMATIC RECORDS OF GROWTH RATE. — The curves given indicate that there are two maxima during the 24 hours; at no time does the maize plant stop growing altogether but at daybreak there is usually a slight decrease in the height probably associated with the opening of the stomata and the loss of water due to the resumption of day time transpiration. This is followed by a rapidly increasing rate of growth until the hotter part of the day is reached when a slight retardation is observed; in the late afternoon there is again an acceleration giving a new maximum about sunset. During the night the growth rate falls off gradually to the minimum just before sunrise. A retardation of growth rate due to the soil water factor is shown in all the curves though only to a slight extent. Measurements made in 1918 by MOSSÉRI in his garden at Giza show the growth of plants during 12-hour periods of day and night, and it appears that growth in the night hours from 8 p. m. to 8 a. m. tends to

be greater than in the day time 12 hours period, doubtless owing to the check during the hotter part of the day.

II. DAILY MEASUREMENTS OF GROWTH RATE ON SELECTED MAIZE PLANTS. — The temperature and humidity records were taken from the mean data for Abbassia and Giza supplied by the Physical Service of the Ministry of Public Works. The curves for the 3 day means are given. The main features brought out are in the first place the effect of irrigation on growth (after each watering there is a marked increase in growth rate) ; this is shown particularly well in the 1919 curves where the soil moistures are given. There is also a fairly close relationship between the temperature and growth rate in the early part of the season, when soil moisture is abundant. This relationship becomes less noticeable as the plant becomes more developed and the soil moisture conditions intervene.

In 1919, an experiment was planned in which soil moisture determinations were made every 2 or 3 days so that as soon as the water content, (depth 20 to 40 cm.) approached 25 % of the dry soil, irrigation was possible. It was found necessary to irrigate more frequently than usual and a slight benefit was obtained in the final yield. Later experiments indicated that with heavy manuring the effect of the water factor on the yield became more marked. The adjoining table indicates that frequent irrigation as controlled by soil moisture gave a yield (stalks and ears respectively) of 4760 kg. and 1510 kg. per feddan, and the yield with normal irrigation (7 times between July 7 and October 22) of 4630 kg., and 1460 kg. There was also an increase in the heights of plants when irrigations were more frequent *e. g.* frequent irrigation, mean height of 40 plants 1) to leaf tip, (18 to 46 days), 55 to 210 cm. ; normal, 55 to 202 cm. ; 2) to tassel (46 to 67 days), — frequent, 158 to 274 cm. ; normal, 151 to 266 cm.

III. WEEKLY MEASUREMENTS AS RESULT OF SOWING EXPERIMENTS. — The normal time for planting maize in Egypt is towards the end of July. In 1919, however, sowings were made from the beginning of April until the end of September and weekly observations were made of the growth and development of the plants throughout the season. The variety employed was the Bahtim "Surecropper", long season semi-dent variety.

Growth and development curves are given for the various sowing dates ; these correspond with the figures given. The physiological development of the plants shows the same characteristics in the curves of leaf development, tasselling, silking and maturation. These features are also brought out according to the isophytic diagram. The best growing conditions for the maize plant in Egypt are evidently to be found late in July and during the month of August. The amount of growth, including time for germination in the first 21 days after planting, shows how far temperature plays a part in determining the rate of development of the maize plants. Germination in the case of the April sowing took place in 12 days, in the May sowing it was 10 days, while in July sowings the time is normally 5 or 6 days. Although the mean temperature at the end of August is about the same as early in June, the night temperatures are more favourable than at the earlier period. The following table shows the comparative

yields of maize sown at different periods and the heights at 21 days after planting.

Date of sowing	Comparative yield * of grain	Height of plant	Temperatures (°C.) Average for 21 days		
			Maximum	Minimum	Mean
April 1 . . . . .	56	24.6 cm	29.6	11.4	20.5
May 1 . . . . .	63	25.1	30.4	12.2	21.3
June 1 . . . . .	84	43.5	33.7	14.8	24.2
June 15. . . . .	88	51.7	34.7	16.2	25.4
June 29. . . . .	92	61.6	36.8	17.4	27.1
July 13. . . . .	100	69.1	36.3	18.7	27.5
July 27. . . . .	96	62.2	35.5	18.5	27.0
August 10. . . . .	86	59.1	35.7	18.5	27.1
August 24. . . . .	—	62.8	33.3	17.1	25.2
September 7. . . . .	64	51.9	31.7	15.4	23.5
September 21 . . . . .	30	—	—	—	—

(\*) Maximum yield in sowing of July 12 being taken as 100.

From a consideration of the mean weekly maximum and minimum temperatures at Bahtim (April to November), it seems clear that the optimum growing weather in Egypt for maize occurs during the month of August; at this time night temperatures are higher than at any other time of the year and during the day time the effects of water strain on the plants is likely to be much less in evidence than during the month of July.

25 - The "Pure Line" and the "Pure Chain": a Contribution to the Terminology of Genetics. — PRELL, G., in *Zeitschrift für induktive Abstammungs- und Vererbungslehre* Vol. XXVI, Parts 3-4, pp. 287-294. Leipzig, July 1921.

PLANT  
BREEDING

The term "pure line", in the sense in which it is used by JOHANNSEN, should be employed exclusively for groups of individuals derived from an autogamous stock by means of repeated self-crossing. It is however often used also to designate groups of genetically isolated individuals derived from two allogamous parents. The necessity of finding a distinct and suitable term for this second class of individuals has long been felt and the author proposes the expression, "pure chain", ("reine Kette").

Thus we have:

**Pure Line.** — The entire group of individuals descended from a single autogamous, homozygous stock.

**Pure Chain.** — The entire group of individuals descended from two allogamous stocks which are isogeneous (isozygotes and homozygotes), only as regards sex and the characters with which they are possibly connected (heterozygotes only as far as sex is concerned).

The two groups differ in the number of diplonts (diploid numbers of chromosomes) necessary to their formation and in the nature of the

relations existing between the haplonts (haploid numbers of chromosomes), that unite to form the diplont. In pure lines, the point of departure is a single diplont, and the whole genealogical tree can correctly be represented as a simple *line*. On the other hand, the pure chain starts from two diplonts, so that in the genealogical development, there are two diplont forms that constantly coalesce and separate according to the same rule, thus producing the exact image of a *chain*.

The haplonts of a pure line are identical, from the genetic and typical standpoint, whereas the haplonts of the chain differ in the factor or group of factors of sex. The contrast between the line and the chain is specially noticeable when there are other morphological factors united to those of sex; in this case, the heterozygotism of a diplont is accentuated.

26 - Study of Barley Hybrids, Especially from the Standpoint of Fixity of the Segregation of Characters in the  $F_2$ . - BLARINGHEM, L., in *Annales de la Science agronomique*, Year 38, Series 6, No 4, pp 177-230 Paris, August 1921.

The visible morphological characters of barley grain are indices which allow varieties suitable for the brewery to be distinguished from those suitable for cropping. These characters are regularly transmitted in a large number of lines and can be used as a test of the botanical purity of each kind.

The author gives the results of a series of experiments relating to two characters 1) hairs on axis of spikelet: *stiff* (A), or *downy* (a); 2) lateral dorsal veins of the seed: *rough* (B), or *smooth* (b). These two pairs of characters behave as independent Mendelian units in crosses between pure form of the variety *Hordeum distichum nutans*.

HAIRS ON AXIS OF SPIKELET. — The pair  $Aa$  obeys the Mendelian law in 29 crosses (with 110  $F_1$  hybrids and 5422  $F_2$  hybrids), between varieties belonging to the Linnaean species, *Hordeum distichum*, *H. nudum* and *H. tetrastichum*. In every case and in all the combinations, the ratio of stiff-haired to downy-haired individuals in the  $F_2$  was as 3:1. This cha-

racter therefore manifests itself independently of the nature of the above-mentioned 3 species upon which it is possible by means of suitable crossings to impress at will the character of stiff hairs or downy hairs respectively.

It remains to be seen whether these characters are of any importance from the industrial, agricultural or commercial standpoints.

The same numerical relations are found in the crosses: *H. distichum nutans* × *H. distichum erectum*, *H. distichum* × *H. nudum* and *H. distichum* × *H. tetrastrichum*.

TABLE II. — Segregation in the  $F_2$   
of Crosses between Forms of *H. distichum nutans* (1909).

0.236 ♀	Bohemia	♂	. . .	629 (640)	481 (480)	148 (160)
0.185 ♂	0.236	♂	. . .	47	36	11
0.185 ♀	0.431	♂	. . .	39	29	10
0.431 +	0.185	♂	. . . . .	36	33	5
0.431 ♀	0.185	♂	. . . . .	24	15	8
Totals . . .				1298 (1300)	986 (975)	312 (325)

DORSAL VEINS. — The pair **Bb** on the other hand behaves somewhat differently from the pair **Aa**. These characters are only independent in the variety *Hordeum distichum nutans* (which includes all the best brewing barleys), and solely in the 1906 crosses. In the  $F_2$ , individuals with rough veins and smooth veins occur in the ratio 3 : 1.

On the other hand much segregation is already found in the crosses made in 1907 (all between forms of *H. distichum nutans*) as is shown in Table III

Similar cases of segregation occurred in 1908: the author suggests, that they may be explained by the greater plasticity of Chevalier II, Hannchen, and the lines 0.190, 0.385 and 0.219 as compared with the lines 0.236, 0.431 and the form Bohemia. If this is the case the pair of characters *presence* — *absence of bristles* would be a more significant association in proving the fixity of the lines than the pair *stiff hairs* — *downy hairs*. This seems to be proved by the behaviour of the hybrids arising from crosses between 0.501 (line of *H. distichum erectum* with smooth veins), and 0.631 (line of *H. distichum erectum* with rough veins). In fact, in the  $F_2$  of crosses made in 1906, in the neighbourhood of Paris, the ratio of bristly individuals to smooth individuals was not as 3 : 1, but as 1 : 1, as if the lines 0.501 and 0.631 were fixed hybrids. In the crosses effected in 1906 out of the 91 (92) individuals of the  $F_2$ , 42 had rough and 49 had

smooth veins, instead of 69 and 23, as there should have been theoretically according to the ratio 3 : 1.

The crosses made in 1907 between the same lines, **0.631** and **0.521**, gave on the contrary different results; in  $F_2$ , the general ratio was 3 : 1 but there were individual variations, such as had not been observed among the former hybrids. Similar results were again produced in the case of cross **0.190** × **0.631** (and **0.631** × **0.190**): the progeny in the  $F_2$  dividing into 3 groups with very different ratios of segregation.

1st group = 3 : 1

2nd " = 1 : 1

3rd " = 9 : 7 or 15 : 1

The difference in the results observed from one year to another deserves notice, as it always occurred in the same types. The essential factor of genetic instability is to be found in line **0.631** (and perhaps also to some extent in **0.190**), but the author maintains that it is owing to the genetic instability of these types that the environment, and more especially the climate are able to alter the percentages (ratios).

This instability would manifest itself in the following manner in the crosses: supposing that **0.631** has a hybrid origin as regards the presence or absence of bristles, and that **A** (presence), is constantly dominant over **a** (absence). In this case, the uniformity and homogeneity characteristic of **0.631** would depend upon the condition that all the egg-cells with the character **A** were fertilised by **a** pollen, and reciprocally that all the **a** egg-cells were fertilised by pollen **A**. Crossing the heterozygous line **0.631** (**Aa**) with the homozygous line **0.190** (**aa**) gives the following combinations :

$$\begin{array}{l}
 \text{I} \left\{ \begin{array}{l} \text{pollen. . . } \mathbf{A} \\ \quad \quad \quad \downarrow \\ \text{ovule. . . } \mathbf{a} \end{array} \right. \quad \text{or} \quad \left\{ \begin{array}{l} \text{pollen. . . } \mathbf{a} \\ \quad \quad \quad \downarrow \\ \text{ovule. . . } \mathbf{A} \end{array} \right. \quad \text{II}
 \end{array}$$

which gives Aa, aA hybrids (with bristles), and aa aa hybrids (smooth) in the proportion of 1 : 1, just as was found in the progeny of the 1906 hybrids and in the 1908 group, *Cistercienne* × *Bohemia*.

This proportion was found in half the cases examined.

The great homogeneity observed in 0.631 is due to prolonged selection under determined (climatic) conditions of environment. Now it is quite possible that the same conditions of growth would act upon 0.631 × 0.190 in a manner quite different from that in which they would act upon 0.631, and that the regular fertilisation of all the 0.631 A ovules with a pollen (and reciprocally), would undergo some modifications (in the cross 0.631 × 0.190). Once the equilibrium is disturbed, the segregation ratios become irregular and vary from one year to another according to the variations of the environment that in any way effect the state of equilibrium.

It still remains to be demonstrated whether under given conditions of climate, soil, date of sowing, cultural operations, etc 0.631 degenerates, in a more or less irregular manner as regards the character of bristles.

Breeding experiments alone can answer this question, and so far, none have been carried out

It is however well to remember that *Svanhals* and *Primus* barleys, of which the genetic constitution is heterozygous, are fixed in Sweden and Germany, but rapidly degenerate (as regards this very character of bristles), when they are cultivated in dry years in Picardy and in Eure-et-Loir (France)

27 - **Studies in Linkage Relations in Maize made in the United States.** — EYSTER, W. H., in *Genetics*, Vol. 6, No. 3, pp. 209-240, tables 32, bibliography of 20 works. Baltimore, May 1921

Results of a systematic search for linkages in maize, especially as regards the two characters tunicate ears (in which the glumes of the ear develop to such an extent that each kernel is entirely enclosed), and sugary endosperm, both dependent on the factor pairs represented as **Tu tu** and **Su su**. In previous tests the author obtained a certain number of reciprocal crosses between the tunicated and sugar heterozygotes (**Tu tu Su su**) and plants non-truncated with non-sugary endosperm (**Tu tu Su su**). The results are shown in Table I. It was estimated that groups **Su Tu**, **Su tu**, **su tu** would be equal. On the contrary however in every case there was an excess of **Su Tu** and **su tu** respectively over **Su tu** and **su Tu**. The tendency of these factors (**Su** and **Tu**) to remain together in inheritance can be explained by assuming that they are located in the same chromosome. But should this follow a fixed rule, the groups **Su tu** and **su Tu** should be missing. Admitting however the undeniable existence of the linkage between **Su** and **Tu**, the resulting exceptions may be explained by the crossing-over theory (1) viz. a certain number of chromosomes are located between the *locus* of **Su** and the *locus* of **Tu**; the chromosomes of the non-tunicated and non-sugary

(1) See R. Jan. 1918, No. 20, note (1) p. 54

plant are located in a similar fashion and the result is an exchange between homologous segments which become united to form new chromosomes; these should possess one only of the two characters previously linked together. The more this phenomenon is intensified and frequent, the more often will **Su tu** and **su Tu** be represented. In the case in question, the percentage of crossing over in the two groups of crosses, should amount to 26.94 and 38.85 % respectively.

The rate of crossing-over can neither be designated, fixed or constant ; it is readily influenced by prevailing conditions and by genetical factors supplied by the chromosomes.

In megasporogenesis (connected with the formation of egg-cells) the percentage of crossing-over in the case investigated, amounted to 21.1 and 30.5 %, while in microsporogenesis (connected with pollen grains), the average is higher than 8 %.

In a second series of genetical experiments the author has made a special study (using a certain number of selected crosses) of the relations between **Tu** and **Su** and other mutant factors :

- C** = colour of aleurone
- Sh** = shrunken endosperm
- I** = factor opposing the production of colour of aleurone
- G** = factor for golden plant
- R** = red aleurone
- B** = brown colour of plant
- lg** = leaves without ligules
- P** = coloured pericarp
- Pl** = purple anthers
- A** = anthocyanin pigmentation in leaves, and grain
- An** = semi-dwarf plants with anthers on the ears
- Bl** = brown blotches on leaves
- Cr** = crinkled leaves
- D** = dwarf plant
- F** = fine striping in the leaves.
- Fl** = floury endosperm
- J** = *Japonica* striping of leaves
- Pr** = purple aleurone in the presence of other aleurone factor pairs
- Ra** = *ramosa* ear
- Gs** = green striping of leaves
- V** = greenish-white seedling
- W** = white seedling
- Y** = factor concerned in the formation of yellow endosperm

The following data refer to the factor **C** (colour of aleurone). In the cross **Tu tu Cc** × **tu tu cc**, the progeny **Su Tu**, **Su tu**, and **su Tu su tu** are obtained in equal proportions (see Table II), which indicates that **C** is found in a chromosome different from that associated with **Tu** and **Su**. Similar conditions appear to exist in the following cases :

TABLE I. — *Linkage between Tu and Su and intensity of the phenomenon « crossing over ».*

28 — **Type and Variability in Kafir (*Andropogon Sorghum*).** — CONNER, A. B., and KAPER, R. E., in *Texas Agricultural Experiment Station, Agricultural and Mechanical College of Texas, Division of Agronomy, Bulletin No 279*, pp 1-14, figs. 6. Brazos County, Texas, April 1921.

The object of this study is to present data as to type and variability of certain characters in *Andropogon Sorghum* resulting from statistical research. The data given are taken from material accumulated from 1915 onwards, involving the measurement of material from crib-run heads and selected population material and from lines successively inbred for single characters. This work was conducted at Texas Agricultural Experiment Station, Substation No. 8, near Lubbock, Texas, a region well adapted to the cultivation of sorghum.

In 1916, 669 crib-run standard blackhull kafir heads were measured and records were made as to :

1) Number of seed-bearing branches ; 2) Length of seed bearing branches ; 3) Number of nodes per head ; 4) Length of rachis or centre stem ; 5) Length of head ; 6) Weight of head ; 7) Weight of threshed grain. In succeeding work with progeny the following additional measurements were taken : 8) Height of plant ; 9) Diameter of plant ; 10) Number of nodes per plant ; 11) Weight of green forage.

The bulletin in question deals however with the first 4 features only. Eighty individual heads were selected for planting in 1917, comprising 8 groups, each group representing one of the extremes of the 4 pairs of characters involved. The selection for the 1918 planting, within a single group, included 10 heads taken from the single row in that group whose progeny conformed to the highest standard for the particular character for which selection was made. Accordingly the selections were made in each generation for a 4-year period. The method of selection adopted is clearly shown in the accompanying diagram. The tabulation of the data for population and for lines inbred for 4 generations is given in the form of tables and graphs, which show the type and variability existing in each population and line from year to year. The tables of statistical constants seem to be quite reliable, judging from the probable error in each case.

The 8 lines involved in every case showed uniformity and purity in the  $F_2$  generation. This is in accordance with the low percentage of cross pollination found by the authors in open-pollinated heads. The practical significance of this fact is two-fold : 1) It lends greater reliability to preliminary uncontrolled breeding work ; 2) It emphasises the value of the head-row method of breeding grain sorghums and gives a greater probability of obtaining pure lines.

The fact that marked progress was made in one only of the 8 lines involved, *viz.* the line selected for few seed bearing branches, emphasises the importance and value of selecting a large number of heads for the initial planting to increase the chances of including superior individuals.

The variability in the several lines, as shown in the tables, is less than in the populations, and is consistently uniform in the  $F_2$  and succeeding generations, further emphasising the purity of the lines in the  $F_2$  generation.

29 - **The Interesting Relation between the Appearance of the Globe Mutant in *Datura Stramonium* and the Behaviour of the Chromosomes.** — BLAKESLEE, A. F., in *Genetics*, Vol. 6, No 3, pp. 241-261. Baltimore, May 1921.

The "Globe" mutant in *Datura Stramonium* is characterised by depressed-globose capsules, by decreased vigour in growth and by the broad and only slightly toothed leaves.

In the *Datura*, the placing and behaviour of the chromosomes are closely associated in relation to the appearance of this mutation and to several others. Consequently there has been noted, in every case, a duplication of chromosomes giving rise to dimorphic gametes with 12 and 13 chromosomes instead of a single normal type with 12. These are called simple trisomic mutants ; in somatic cells one of the 12 sets is a trisome with three homologous chromosomes instead of the normal two.

1) When selfed, the mutant character is passed on to about 22 % of the descendants.

When crossed with a normal as the male parent, the mutant character is transmitted to about 26 % of the progeny. If however the pollen of a mutant is employed, the abnormal character is apparent in only about 2 % of the progeny.

The author has concluded therefore :

a) As a general rule, the mutant complex is transmitted through the egg cells and either not at all or only to a very limited extent through the pollen.

b) By crossing the mutant (♀) with the normal (♂), the number of mutants obtained in the progeny was inferior to that expected, which may be attributed to the lessened vitality of the mutant forms. Selfing continued for 10 generations has not increased the proportion of mutants in the progeny.

2) New Globe mutations under normal conditions have occurred in about 0.05 % of the descendants (1 out of 2000 individuals). The percentage is, however, distinctly higher, in cases which already contain the simple trisomic mutants. It is also higher when the mutant is used as the female parent, but when crossed with normals, there is no increased percentage of mutants in the progeny. It may be concluded therefore that new Globe mutations are caused by changes in the formation of the egg cells and rarely by changes in the pollen.

3) Normal plants show about 2.7 % of defective pollen grains; Globes about 8 %. The pollen sterility is then a characteristic of the Globe, as it is of the other simple trisomic mutants.

30 - Number of Chromosomes in Various Species of *Lactuca* (1). — MITSUHASHI ISHIKAWA, in *The Botanical Magazine*, Vol. XXXV, p. 130 Tokyo, July 1921.

The author has made a special study of the number, behaviour and size of 15 species and 5 varieties of *Lactuca*, several of which are found growing wild in Japan; the figures in brackets indicate the number of chromosomes.

<i>L. laciniata</i>	(9)	<i>L. chelidoniifolia</i>	(5)
<i>L. Raddiana</i>	(9)	<i>L. debilis</i>	(24)
<i>L. triangularis</i>	(9)	<i>L. stolonifera</i>	(8)
<i>L. Scariola</i> var. <i>sativa</i>	(9)	<i>L. repens</i>	(8)
<i>L. villosa</i>	(9)	<i>L. Matsumurae</i>	(8)
<i>L. Keiskeana</i>	(5)	<i>L. tamagawensis</i>	(8)
<i>L. lanceolata</i>	(5)	<i>L. chinensis</i>	(16)
<i>L. lanceolata</i> var. <i>platyphylla</i>	(5)	<i>L. dentata</i> var. <i>gemma</i>	(12)
<i>L. denticulata</i>	(5)	<i>L. dentata</i> var. <i>albiflora</i>	(12)
<i>L. denticulata</i> var. <i>pinnatifida</i>	(5)	<i>L. dentata</i> var. <i>alpicola</i>	(7)

As regards size and shape and number of chromosomes, 5 groups were distinguished, showing differences also of a general taxonomic nature.

(1) See *R. Feb.* 1918, No. 180 (Ed)

NAKAI has previously stated, taking as a base the morphological characteristics, that the Japanese species of *Lactuca* may be classified under 4 headings, *Lactuca*, *Crepidiastrum*, *Paraixeris* and *Ixeris*.

It is of interest to note that the two classifications, made according to the two different standpoints (taxonomic and cytologic) are in agreement. *Lactuca* corresponds to group 1, *Crepidiastrum* to group 2, *Paraixeris* to group 3, and *Ixeris* to group 4 and to a fifth group constituted by the author (1).

31 - The "Akala" (*Rubus Macraei* Gray), an Endemic Hawaiian Raspberry and the Possibilities of its Improvement by Hybridisation and Selection. --

ROCK, J. H., in *Journal of Heredity*, Vol. XII, No. 4, pp. 147-150, figs. 3, Washington. April 1921

The Akala berry grows wild in Hawaii and possesses varying characteristics, which permit a subdivision into several distinct varieties.

In Kanaï, it is an upright spineless shrub, only a few feet in height, with somewhat small, dry berries.

In Maui the plants resemble to a certain extent the typical species from Hawaii, but have more spines and the fruits are less than half the size.

*Rubus Macraei* prefers the slopes of the high mountains of Hawaii proper (on Hualalāi, Mauna Loa and Mauna Kea). The largest fruited specimens were discovered by the author in a volcanic cone, known as Hinakapanulla, situated 6000 ft. high, in a desert lava field. The Akala was found in abundance with *Acacia Koahawaiiansis*, *Coprosma pubens*, *Styphelia tameiameia*, and presented the appearance of a huge liana several feet long and with a woody stem 2 inches in diameter. The berries, of a dark rich purple colour were at least 2 inches in diameter. The plant is completely devoid of spines.

In the fern forests near the volcano of Kilanua there occurs another form of *Rubus Macraei*, also spineless, at least in older plants. This region has been given over to cattle grazing, and consequently the akala has gradually disappeared as a terrestrial plant and only the plants which became epiphytic have survived. These grow in the crevices of trunks and branches of trees and in the forks of moss covered trees. Although smaller than the berries found on the Hualalei and Mauna Kea Islands, they are always over 1 1/2 inches in diameter in spite of the lack of humus and of real soil.

(1) The unit characters to which may be applied or to which there is a tendency to apply Mendelian laws are regulated by the genetic factors in the chromosomes. Recently, the researches made in Japan and the United States (MORGAN etc.) have thrown considerable light on the question of chromosomes in the hereditary sense, and it has been concluded that a parallelism and intimate connection exist between the unit characters of the plant and the behaviour, number and forms of the chromosomes. The characteristics on the one hand and on the other, the chromatic constant which corresponds, constitute the two extreme points of the genetical inquiry. If much has been said and written hitherto concerning the characters, nothing really definite has been arrived at which confirms cytologically the Mendelian principles. It is therefore advisable to keep the plant breeding section well informed as to the most recent investigations on this subject. (Ed.)

The author has collected a number of species, especially on the windy slopes (6000 ft. elevation) of Mauna Kea. The air is always cool, the nights even cold, frost not being uncommon in winter. Every day after 11 o'clock the clouds ascend from the sea and the slopes of the mountain become shrouded in fog for the greater part of the day. Two distinct varieties are found; one dark purple and the other bright orange yellow; the first was almost spineless and the second was spiny. The fruits are very juicy and the seeds quite small; the dark variety is slightly bitter, while the yellow is quite sweet. Hybridisation should result in obtaining valuable types, specially adapted to slopes on the Pacific coast line with mild winters and liable to fogs.

- 32 - "Tangelolo", a New Citrus Fruit Obtained by Crossing the "Sampson Tangelo" with *Citrus decumana*. — SWINGLE, W. T., and ROBINSON, T. R., in *The Journal of Heredity*, Vol. XII, No. 4, pp. 151-153, figs. 1. Washington, April 1921.

In 1908 at Eustis (Florida), a new cross was obtained by using the pollen of the Sampson Tangelo, a hybrid resulting from using pollen of the Dancy tangerine on grapefruit (*Citrus decumana*).

Two of the seedlings thus obtained have fruited. The fruits resemble the male parent in general appearance (size, shape and character of rind), but on cutting, the colour of the pulp or rather the lining membrane and partition walls were found to be reddish pink. This colour often shows in small blotches on the rind which appears to be free from any bitterness or pungent oil and consequently very mild and edible.

With this characteristic and the attractive colour of the pulp, the fruit lends itself especially to the preparation of jams etc.

The marked influence of the male pollen is not only evident in the size, shape and exterior appearance of the fruits, but also in the characteristics of the leaf which is large and rounded. Cultural tests are at present in progress with a view to the establishment of the economic value of this new hybrid and to ascertain the possible advantage of the continuation and propagation of this fruit.

- 33 - Determination of the Origin of Linseed on the Market. — P. FILTER (Landwirtschaftliche Kontrollstation, Berlin), in *Die Landwirtschaftlichen Versuchstationen*, Vol. XCVIII, Parts 5-6, Berlin, 1919.

The determination of the origin of the different linseeds of commerce is sometimes a matter of great importance, for the oil content, rapidity of drying, impurities, etc. differ considerably according to the country from which the linseed comes. Thus Bombay linseed contains, on an average, 43 % of oil, Russian linseed about 37 % and Japanese linseed 35 %.

The author directed his attention chiefly to the investigation of linseed from the principal sources of the world's supply — Argentina, British India, North America and Russia, but he also extended his examination to linseed sent from China, Japan, Persia, Morocco and Turkey. The results are set forth in a series of tables from which are taken the averages given in the following Table. In order to determine the fat

content, the seed was first coarsely crushed and extracted with anhydrous ether, then finely ground and again extracted, 2 to 3 % more oil being obtained by the second operation. The drying was effected by a current of gas.

The oil content found by the author is generally a little higher than that given by HASELHOFF (*Landw. Versuchs-Stationen*, 1892, Vol. 41, p. 58), or by SCHINDLER (G. HEFTER, *Technologie der Fette und Öle*, p. 7).

As a rule, the weight of 1000 grains is greater in tropical and sub-tropical countries and less in the temperate, and it thus affords some index of the origin of the linseed.

The fat content is of much less significance; the position of the country of origin in this respect is as follows (in descending order). British India (Bombay) — Turkey — British India (Calcutta) — China — Morocco — Argentina — South Russia — North America — Persia — North Russia. The fact that the oil content varies considerably in the same place according to the year, greatly detracts from the value of this character in the identification of the origin of linseed.

The impurities are of much more importance in this respect, especially those classed as "characteristic weed seeds", for they nearly always indicate the country of export.

*Characters of Linseed of Different Origins.*

Source	No of samples analysed	Fat content	Water content	Weight of 1000 grains	Coefficient of purity
Argentina . . . . .	25	39.68%	4.96%	6.0272 gm	97.6%

Persia . . . . .	2	38.55	4.22	5.5025	95.6

The author gives for each country of origin the list of the weed seeds found among the impurities; he also gives a Table showing the distribution of the total number of the weed seeds discovered (141 species). These data allow the characteristic species to be determined for the various countries as follows:

ARGENTINA. — Characteristic species: *Ceratochloa australis* (Bro-

*mus unioides*) — *Brassica campestris* — *Anthemis Cotula* — *Melilotus parviflorus* — *Lolium brasilianum* Nees — *Centaurea melitensis* — *Rumex pulcher* — *Phalaris minor*; accessory species: *Silybum Marianum* — *Silene gallica* — *Lolium temulentum*. As the seeds of several species of these weeds are always present in large numbers there is no difficulty in recognising linseed from Argentina, the country which supplies most of the linseed to the markets of the world. The absence of *Cuscuta epilinum* is characteristic.

NORTH AMERICA (UNITED STATES AND CANADA). — The weed seeds chiefly found in linseed from these countries are: *Grindelia squarrosa* — *Helianthus annuus* — and *Sisymbrium Sinapistrum*. The two first species are exclusively North American, the third is also found in linseed from South Russia. Accessory species. *Erysimum orientale*, *Polygonum Convolvulus*; other species of *Convolvulus* and *Cuscuta epilinum* are absent.

BRITISH INDIA (BOMBAY AND CALCUTTA). — Typical impurities: *Brassica campestris* var. Sarson (= *Sinapis glauca* Roxb — *Brassica glauca* Wittm) — *Brassica dichotoma* Prain — *B. juncea* H. f. and T. — *Asphodelus tenuifolius*. The three first are typical Indian varieties. The following are also found: *Lathyrus sativus* var. *indicus*. — *Cicer arietinum* (variety with small brownish-red seeds) — *Gurztia abyssinica* — fragments of the integument of *Ricinus communis*. Indian linseed is easily recognised owing to the constant presence of Indian species of *Brassica*.

As linseed from Calcutta and Bombay contains the same impurities, they are of no assistance in discriminating between the two products, which can however be distinguished by the weight of 1000 seeds and the oil content, both of which are higher in Bombay than in Calcutta linseed as is shown by the Table.

NORTH RUSSIA. — This term is chiefly applied to the eastern maritime provinces. The following characteristic impurities are always present in large quantities: *Polygonum lapathifolium* — *P. Persicaria* — *Lolium remotum* — *Spergula maxima*. None of these species is exclusively Russian but taken together they form a characteristic feature.

Accessory species: *Camelina dentata* — *C. sativa* — *Centaurea Cyanus* — *Chenopodium album* — *Galeopsis Tetrahit* — *Thlaspi arvense* — *Matricaria inodora* — *Galium Aparine* — *Anthemis arvensis*. The Japanese linseed resembles the Russian in containing *Spergula maxima* and *Lolium remotum*, but differs from it in being free from *Polygonum lapathifolium* and *P. Persicaria*.

SOUTH RUSSIA. — Characteristic impurities. — *Sinapis — dissecta* — *S. alba* — *Brassica elongata* — *Melilotus officinalis* — *Brassica Besseriana* Andr. — *Coronilla varia*. As the impurities are generally very numerous and include the seed of more than one species, it is nearly always possible to recognise linseed of South Russian origin.

Accessory species: — *Sinapis arvensis* (more common in this linseed than in any other) — *Eruca sativa* — *Convolvulus arvensis* — *Panicum milliaceum* — *Vaccaria parviflora* — *Setaria viridis* — *Glaucium corniculatum* — *Allium rotundum* — *Raphanus sativus*. All these species are

also to be found in linseed from other localities, but taken together, they are very characteristic of South Russian linseed.

It is thus evident that there is a distinct difference between linseed from North and South Russia respectively. Linseed from Siberia (of which only one sample was examined), contains the impurities characteristic both of the South Russian (*Sinapis dissecta*), and Chinese (*Corispermum hyssopifolium*) products.

MEDITERRANEAN COUNTRIES (MOROCCO, TURKEY). — It is not difficult generally speaking to recognise linseed from the Mediterranean region, but there are variations in the products of the different countries and the Moroccan and Turkish linseed examined presented very marked differences. The following species of weed seeds characterise the linseed of the Mediterranean countries: *Torilis nodosa* — *Arthrolobium scorpioides* — *Bupleurum protractum* — *Chrysanthemum coronarium* — *Cephalaria syriaca* — *Phalaris brachystachys*, *Ph. canariensis*, *Ph. paradoxa* — *Bromus maximus* — *Trigonella Foeniculum-graecum* — *Silene cretica* — *Raphistrum orientale*. The Morocco linseed contains special impurities in the form of *Bromus maximus*, *Chrysanthemum coronarium*, and *Bupleurum protractum*; Turkish linseed contains *Silene cretica* and as accessory species: *Asperula arvensis* (very common) — *Salvia Sclarea* — *Rapistrum orientale* — *Coriandrum sativum* — *Scandix Pecten Veneris*.

CHINA. — Characteristic species: *Corispermum hyssopifolium* — *Brassica Besseriana* Andr. (sub. species with yellow seed) — *Polygonum tataricum* — *Salsola Kali* — *Setaria italica*. Considerable numbers of the seeds of the yellow-seeded variety of *Brassica Besseriana* are found in Chinese linseed. The following are common as accessory species: *Setaria glauca*, *S. viridis* — *Panicum miliaceum* — *Eruca sativa*.

JAPAN. — Linseed from this country greatly resembles the linseeds grown in North Russia; it also contains: *Lolium remotum* — *Spergula maxima* — *S. arvensis* — *Camelina dentata* but is free from *Polygonum lapathifolium* and *P. Persicaria* which are common in linseed from N. Russia. *Brassica Napus* was only found in Japanese linseed. The presence of fragments of rice and of rice glumes serves also to distinguish Japanese linseed which is further characterised by the very light weight of 1000 seeds.

CEREALS  
AND  
PULSE CROPS

- 34 - Possibility of Growing Wheat in the State of Piahy, Brazil (1). — CABRAL, J. C., in *Brasil Agrícola*, Vol. VI, No. 2, pp. 12, fig. 1. Rio de Janeiro, August 1921.

Dr. João CABRAL, the Deputy for Piahy, on the occasion of his visit to the Professional Agricultural Institute at Corrente, noticed a regularly-developed plot of wheat in the experiment field of the Institute.

(1) This is the nearest point to the Equator at which wheat has hitherto been grown in Brazil. It is said, that this cereal was cultivated in Pará by the first colonists, but that rust drove the wheat plant continually southwards. For some years however a fresh attempt has been made to increase wheat production and positive results have been obtained from experiments carried out in numerous places in the state of Minas Geraes. It is quite impossible to grow wheat beyond the northern limits of this State, but as soon as Bahia is reached, this cereal is cultivated with *Hevea*, cacao, and manioc, at only 8° south latitude.

The climatic conditions of the State of Piahy are similar to those in North-east Brazil, where the copious rainfall and high temperature are favourable to the cultivation of rubber and manioc.

35 - **Kanota: An Early Oat Introduced into Kansas, United States.** — SALMON, S. C., and PARKER, J. H., in *Agricultural Experiment Station, Kansas State Agricultural College, Circular 91*, pp. 1-13, tables 61, figs. 2. Manhattan, Kansas, August 1921

Kanota oats were first grown at the Kansas Agricultural Experiment Station in 1916 when 4 lots of seed from Texas, all called Red Texas or Red Rustproof were received. Kanota belongs to the red oat group, *Avena sterilis*, characterised by a brownish red coloured grain, sucker mouth and basal hairs. The awns, however, are usually missing or, if present, are poorly developed and the young plants assume at an early age a semi-erect position. These three points appeared to differentiate it distinctly from the Red Texas oats. Kanota appears to occupy an intermediate position between the red and white groups which suggests hybrid origin with characters associated with *A. sativa* (northern) and *A. sterilis* (southern) and this may explain its geographic adaptation.

As regards the appearance of the grain, Kanota is identical with other Fulgum strains, but the difference in certain agronomic characters and in agronomic value is evident according to the experimental results obtained at Kansas 1917-20. The average yield for the 4 years has been 47.1 bushels per acre which is 10.9 bus. more than Red Texas, the variety previously regarded as the best available oat.

Kanota was first tested by Kansas farmers in 1919 and the table giving the comparative yields of this variety and a local strain of Red Texas shows a difference in favour of the first named variety, amounting to 15.3 bus. Further results in 1920 also demonstrate the advantages of adopting the Kanota variety.

According to the Table giving the dates of heading and ripening, Kanota evidently possesses the advantageous characteristic of early maturity. In early spring growth it resembles the white oat (*A. sativa* group), and in 1919 when this factor seemed to be a determining one with respect to production, Kanota made as rapid a growth as any other variety, tillered abundantly, and was not seriously hindered in its growth by weeds. All strains of Red Texas on the other hand made very slow vegetative growth, were damaged by weeds and gave low yields.

In field plot tests, Kanota produced grain of better quality than other varieties as regards weight. As indicated by the table, the average test weight was 5 lb. higher than Red Texas, 3 lb. higher than Burt and 8.1 lb. higher than the most productive Kherson; the average weight for the years 1917-20, was 33.7 lb. per bus.

In nursery and field plot tests the straw has been found to be slightly shorter than in other varieties, but there seems no reason to fear that the straw will be too short to bind and where lodging is likely to occur the short characteristic may be advantageous.

Observations made in the springs of 1920 and 1921 at Manhattan and

Hays, indicate that Kanota is somewhat more resistant to late spring frosts than Kherson oats and fully equal if not superior to Red Texas in this respect.

As regards resistance to disease, although Kanota belongs to the "red rust-proof group" *A. sterilis*, it is not resistant to *Puccinia coronata* nor to *P. graminis avenae*. However, although not immune from smut, (*Ustilago Avenae*), it shows a high degree of resistance.

It is estimated that about 8000 bus. of pure seed will be available for sowing purposes in the spring of 1922. It is proposed to inspect the crop and publish a seed list each year so that a supply of reasonably pure seed will be available at all times.

36 - Varieties of Rice Tested in 1921, in the Experiment Field of the "Granja arrocería" of Sueca, Valencia, Spain. — MONTESORO, E. G. (Director de la Granja arrocería de Sueca), in *Boletín arrocero*, Vol. VII, No. 98, pp. 1-3. Valencia, November 26, 1921.

Tests were made with 18 varieties divided into 3 groups: I) varieties that had already been tried for some years and were therefore acclimatised; II) New varieties imported from the Royal Riscultural Experiment Station of Vercelli (Italy); III) Varieties sown and transplanted at two different times.

GROUP I. — Kukurio — Pelarda Précoce — Brasileño — Montesoro Précoce — Vialone nero and Vialone giallo, considered as a single variety — Bomba (Novelli Précoce, and Matusaska, were also tried, but they proved unsatisfactory and are not to be recommended to rice-growers on account of their low productivity).

As regards unit production, the above varieties are arranged in the preceding paragraph, in descending order, for they yield respectively: 6790 — 6100 — 5703 — 5294 — 4765 — 3646 kg. of paddy per hectare.

Brasileño is in process of degeneration. Montesoro Précoce, Pelarda Précoce, and Bomba are all remarkable for the fine quality of their grain.

GROUP II. — Précoce No. 6. — Isen — Dellarole — Mompel — Allorio — Onsen.

The three first varieties produced respectively 6101 — 5499 — 5102 kg. per hectare; the three last each produced about 3600 kg. per hectare; therefore their introduction is advisable. All these varieties must first be acclimatised.

GROUP III. — The Creppi, Originario 1, Originario 3 and Novelli Précoce varieties should be sown a little later than the others, for they are very early. Montesoro Précoce and Pelarda Précoce may be sown at the usual date.

\* \* \*

This article is followed by a comparative study of the results obtained from the different varieties in the experiment fields of Sueca and Albe-rigue.

- 37.— **Moki Lima Beans (*Phaseolus lunatus*) in Egypt.** — FORBES, R. II., in *Bulletin No. 9 Sultanic Agricultural Society, Technical Section*, pp 1-22, tables 3, figs. 3. Cairo, 1921.

The semi-dwarf habit of growth, the non-twining vines, the endurance of arid conditions of climate and the markings of some of the seeds indicate that the Moki limas probably constitute a distinct group of horticultural varieties within the *Phaseolus lunatus* or Sieva classification. The two first characteristics permit cultivation as a field crop while the leguminous character of the plant and the nutritive value indicate a high food return with minimum drafts upon the soil. Of the colour variants, the White Moki is the most promising commercially.

About 4 months of warm weather are required to mature a crop of dry beans, they are therefore at an advantage in sub-tropical climates where a long season allows time for a succession of plantings.

According to the growth curves taken on monthly plantings made at Giza, stimulated vegetative growth is apparent during the more humid warm weather, July to October inclusive, although the best yields of beans are not necessarily associated with a rapid growth of vines. The marked drought resistant characteristic has also been demonstrated at Giza.

A small percentage only of the bloom develops pods, usually early in the blooming period and according to fertility of soil and space for development of the plant. Data as to the relation of blooms to pods in successive plantings are given and data relative to the setting of pods on several varieties of lima beans shows the highest setting for pods for the Moki lima possessing non-twining vines of medium length.

Owing to the long season (March to August) during which Moki limas may be planted in Lower Egypt, this crop is prospectively available for an unusual number of rotations. Following winter vegetables such as lettuce, cabbage, cauli flower, etc, it may be planted in March and harvested in July in time to be followed by quick maturing varieties of maize. Following broad beans it may be planted in May and harvested in September in time to be followed by wheat and barley. Following wheat and barley it may be planted in June and harvested in October, preceding cotton. It may be planted in July instead of maize and harvested in November preceding berseem (*Trifolium alexandrinum*) or cotton. Following winter rainfall it gives promise as a dry farming crop along the Mediterranean coast and in Palestine.

A description is given of the cultural methods employed in Egypt. Normally this leguminous crop should not require fertilisation under existing conditions, contributing to rather than drawing from the nitrogen supply; but until the required strain of *B. radiculicola* for this bean is available an application of 100 to 200 kg. of nitrates per feddan (1 feddan = 1.038 acres) will increase the yield.

However cultures of *B. radiculicola* from the U. S. Department of Agriculture have finally been established and abundant tubercles produced in experimental cultures with prospective improvement in yield and soil

value. The author gives an outline of 10 different attempts with cultures from various sources.

Insect pests and diseases have not thus far seriously menaced the plants or the crop. Grasshoppers (*Euprepocnemis plorans*), *Etiella zinckenella*, *Bruchus irseectus* have attacked the crop, but these attacks have been successfully controlled.

Under favourable conditions and with proper culture the crop should yield under irrigation 800 to 1000 kg. of good marketable beans in about 4 months time. This estimate approximates to the yield of lima bean in California, where the crop averages from 510 kg. per acre on ordinary land to 910 kg. in the best bean growing sections.

The cost of Moki lima culture based on experience at Balitim Farm has been estimated as follows, two estimates being submitted, for high and low costs of labour respectively. The total cost based on war prices with labour at 10 to 12 piastres per day (July 1920) is estimated at 13.84 £ Egyptian and the total cost based on lower prices with labour at 4 to 7 piastres per day is estimated at 10.32 £ Egyptian. The detailed cost of each cultural operation is notified. The profits per feddan of this culture, under various conditions may be estimated as follows:—

	600 kg 6 piastres per kg. £ (Egyptian)	800 kg 6 piastres per kg. £ (Egyptian)	600 kg 4 piastres per kg. £ (Egyptian)	800 kg 4 piastres per kg. £ (Egyptian)
Gross income . . .	36 00	48.00	24 00	32.00
Costs . . . . .	13 84	13 84	10.32	10.32
Net per feddan . . .	22.16	34 16	13 68	21 68

An analysis was made by PRESCOTT (Société Sultanique d'Agriculture) of samples collected from various sources including both original Arizona seed and successive crops grown in Egypt from this seed. According to the data presented the average of water free material in all Moki limas grown in Egypt, non tuberculous, showed 2.84 % nitrogen and 38.0 % starch (1918-1920). In approximately equal quantities these limas may be used in combination with starchy foods, especially maize (27.75 kg. of limas combined with 24.34 kg. of maize, assuming that the balanced ration for a sub-tropical population should average 1:5).

The author adds recipes which suggest the possibilities of using Moki limas as a food which should make a healthy substitute for meat in a hot climate.

38 - **Lentil-Growing in Brazil.** — *Chacaras e Quintas*, Vol XXIV, No. 3, pp. 207, fig 1. São Paulo, September 15, 1921.

Concise rules for the cultivation of the lentil (*Ervum Lens*), in Brazil are given in this paper. Agriculturists are advised to increase the acreage under this crop, as lentils fetch the good price of 14-15 *milreis* per sack (1 gold *milreis* at par = 2.83 fr.), and the exporters of Rio Grande do Sul are unable to satisfy all the demands made.

39 - **Yam Culture (*Dioscorea* spp.), in Porto Rico.** -- KINMAN, C. F., in *Porto Rico Agricultural Experiment Station, Bulletin No. 27*, pp. 2-22, pl. 6. Washington, 1921.

The yam is one of the important foods of Porto Rico where the climatic conditions favour its growth. It is well adapted to various types of soil, although giving the best results on heavy clay soils. This crop has however been very little cultivated in other countries and in certain cases is practically unknown. In view of the fact that high prices for foods are prevalent, and that yam is among the least expensive of food crops, the description of the general practices adopted in Porto Rico as regards this crop are worthy of attention. Experiments with a view to the introduction of new and improved varieties and methods of culture have been in progress at the Porto Rico Experiment Station for several years.

A description is given of the preparation of the land, and it is stated that ridges of well-stirred soil and vegetable matter should be made sufficiently large when planting to enable the roots to make a normal growth above the water level in the soil and above the firm subsoil. The plants should be placed from 1 to 2 ft. apart in these ridges, according to conditions peculiar to the root growth of each variety. Either entire or sections of roots may be planted, but the upper section has been found to give the most satisfactory results. Dipping in Bordeaux mixture was found to be an effective means of preventing decay of roots cut in pieces for seed. Applications of fertilisers did not result in sufficient increase in the crop to warrant their recommendation, but when used, none of the elements (nitrogen, phosphorus, potash) should be omitted. The table showing the average yield per hill, ridge planting, of 4 varieties of yams on fertilised and unfertilised plots confirms this statement.

Tests in cutting back the vines have demonstrated that vines should not be touched or injured if the best results are to be obtained. Where also the vine supports are insufficient there is a marked decrease from the normal yield.

Among the varieties commonly grown in Porto Rico, the one known as Guinea (var. *Dioscorea sativa*) is the most popular on account of its heavy yield, its high food value and its pleasant flavour. Other varieties here described in detail include the Potato Yam, (introduced from Africa), identified by WESTER as *D. aculeata*, Purple Ceylon, S. P. I. No. 31922 (var. *D. sativa*), S. P. I. No. 31920, *D. Chondrocarpa*, Agua (var. *D. alata*, introduced from New Guinea), Yellow Guinea (var. *D. Cavennensis*), and Mapuey Morado. The last is considered superior in flavour to any other yam, but the yield is low.

40 - **The Chemical Composition and Yield of Forage-Maize Cut at Different Stages, in Hungary.** -- WEISER, S., and SATTSCHKE, A. (Königl. ungar. tierphysiologischer Versuchsstation in Budapest), in *Die Landwirtschaftlichen Versuchsstationen*, Vol. XXVII, Parts 1-2, pp. 111-130. Berlin, 1920.

FORAGE CROPS,  
MEADOWS  
AND PASTURES

In previous experiments carried out by the authors to determine the effect that the space left between the plants has upon the unit production

and nutritive value of forage-maize, the question arose as to the stage at which maize should be cut for silage, with a view to obtaining the heaviest crop per hectare (*Landwirtschaftliche Versuchs-Stationen*, Vol. LXXXI, p. 49, 1913).

In order to be able to answer this question, the authors made experiments in several places in Hungary for the purpose of discovering the chemical changes that take place in the plant, and the yield of crude nutritive substances per hectare from the time of the appearance of the male inflorescences.

Samples were taken at regular intervals until the plants withered and their leaves began to fall. A series of tables gives : 1) the composition of maize in its natural condition at the different dates of cutting and in the various localities — 2) the composition of the dry matter — 3) the water content of maize cut at different stages — 4) the amount of dry matter, and of each of its constituents, per surface unit obtained in every place, in the case respectively of a minimum, average and maximum crop; the increase taking place during maturation per 100 gm. of each of the constituents or of the total dry matter — 5) the percentage distribution of the total dry matter and of each of its constituents in the places where the maize was cultivated.

The water content of maize plants cut at the time of the appearance of the male inflorescences varied from 83.4 to 89 % and the average in 11 experiments was 87.23 %. KRIEGER gives 80.6 % as the mean water content of forage maize, but these researches show that 13 % is the maximum amount of water present in Hungarian maize. The loss of water sustained during maturation, and hence the increase in dry matter varies from one locality to another. On an average the daily increase in dry matter from the time of the appearance of the male inflorescences, until 20-76 days later was 0.24 % and the weekly increase 1.5 %. Green maize with an average dry matter content of 12.8 % at the moment of development of the male inflorescences, contained 20.6 % thirty days later and was so dry that it could no longer be fed as green forage.

The ash content of forage maize at the time the male inflorescences appeared varied from 0.66 to 1.5 %. In most of the varieties used in the experiments the mineral content of the plants showed no further increase from this date ; in 2 cases only out of 12 was there any noticeable increase. It is certain that the character of the soil and the nature of the fertiliser used determine the time at which the plant ceases to absorb mineral substances, but the absorption of these substances never proceeded parallel with the increase of dry matter. The dry matter ash content continued to rise until it reached the maximum, and then fell during 4 to 5 weeks, until it was about half the amount first observed : on an average from 7.37 % to 4.88 %.

The forage-maize protein content (both crude and pure), increased but little during the maturation process, and did not proceed *pari passu* with the increase in dry matter. The average of all the experiments was as follows.

	Crude protein	Pure protein
At the time of the appearance of the male inflorescences	1.07 %	0.86 %
In ripe maize . . . . .	1.26	1.03
In the dry matter on the appearance of the male inflorescences . . . . .	8.44	4.93
In the dry matter at maturity. . . . .	6.77	4.06

The ether extract content of a green plant at the time of the appearance of the male inflorescence was 0.48 %, and during the drying that accompanies maturation it rose to 0.76 %, whereas at the same time, the crude fat content of the dry matter fell from 3.76 to 2.40 %. It is certain that the composition of the crude fats also changes during this period, for often during the maturation of forage-maize, ears containing well-developed grains are produced, whereas on the other hand, the amount of chlorophyll progressively decreases.

In the ether extract of green maize, the authors only found 3 % of pure fats and 97 % of unsaponifiable matter, but in maize in process of ripening, the crude fat content continually increases while the non-fatty substances diminish.

The amount of crude fibre increases without intermission during the plant's development and until its complete maturation; on an average it rises from 3.29 to 6.35 %.

The fibre content of the dry matter nearly always remained constant; it was 26.7 %, on an average, at the time the first sample was taken, and 25.2 % when the second was gathered. This proves the incorrectness of the generally-received opinion that the fibre content of the dry matter present in maize is much larger some weeks after the development of the male inflorescences than at the date of their first appearance. The lignification of maize, which is connected with the drying accompanying maturation, cannot thus be explained by the increase in fibre, but must be attributed to other causes. It might be supposed to depend upon variations in the proportions between the 3 groups of substances composing crude fibre: cellulose, lignin and cutin, but the authors have found that there is no essential difference in the fibre composition of maize cut at different stages and therefore the cause of the process must be sought elsewhere.

The amount of nitrogen-free extract varies in green maize from 7.02 % to 15.7 %, and in the dry matter, from 54.75 % to 62.57 %. These extracts thus continue to increase during the maturation process.

The amount of dry matter produced by a plant varies from 5.03 gm. to 23.11 gm. at the time of the appearance of the male inflorescences; later the variations are still greater. There are also great differences in the number of plants per sq. metre and in the quantity of crude nutritive substances produced per sq. metre. In three experiments made at the same place (Jászberény), 282 — 301 — 182 gm. were obtained respectively from 100 gm. of dry matter in 59 days; at Debreczen, 648 gm. were obtained in 55 days; and at Kassa, 204 gm. in 60 days.

In the various localities the largest amount of dry matter was produced at different times after the appearance of the male inflorescences, and this is due to the different exposure of the fields and to the dissimilar climatic and cultural conditions. If the latter are favourable the amount of dry matter increases 4 to 5 times, otherwise it is only doubled. As the areas planted were of very limited extent, the results of these experiments are not absolutely applicable to practical work; they however show that after the male flowers have appeared, the plants continue growing for 7 to 8 weeks and the dry matter goes on increasing all this time. Maize for silage should thus be left standing as long after the appearance of the male inflorescences as is possible without its beginning to lignify (1 or 2 weeks). In this way twice to six times more dry matter is obtained than if the plants had been cut as soon as the tassels were formed, or a little earlier or later. The chief increase in dry matter takes place during the 8 to 20 days following the appearance of the male inflorescences.

From the beginning to the end of the experiment, the culm's growth in length and circumference always kept pace with the increase in the amount of dry matter per surface unit.

In the case of all the varieties used in the experiment the dry matter content was increased by the addition of the same substances. These consisted for the most part of carbohydrates, and to a considerable extent, of cellulose, that is to say, of the constituents which give maize its nutritive value.

The authors' experiments with oxen showed the digestibility coefficient of the nitrogen-free extracts, and of the cellulose to be respectively 76 %, and 59.90 %, whereas that of pure protein is only 55 %, so that the content in the latter element present in maize for ensilage is of no practical importance. The average percentage composition of the dry matter formed after the appearance of the male inflorescences was as follows: Ash 4.26 — Crude protein 3.60 — Pure protein 2.82 — Crude fat 1.98 — Fibre 25.56 — Nitrogen-free extracts 64.60.

As the composition of the crude fibre, like that of the nitrogen-free extracts does not perceptibly vary during maturation, the digestibility of ensilaged maize is practically independent of the time at which it is cut. The losses taking place during ensilage are also but little affected by the age of the maize used. From the point of view of forage use there is no objection to putting quite ripe maize in the silo. It should be cut at the time of the greatest production of dry matter and before any has been lost as a result of the falling of the leaves, etc.

41 - **Experiments in Growing Italian Rye-Grass (*Lolium italicum*), in Brazil.** —

DE SOUZA, Pedro P. (Director do Posto Zootécnico, Viamão, Rio Grande do Sul), in *Chacaras e Quintais*, Vol. XXIV, No. 3, pp. 193-194, figs 2 São Paulo, September

15, 1921

The author has tried growing both Italian rye-grass (*Lolium italicum*), as well as English rye grass (*Lolium perenne*), on the farm annexed to the « Posto zootécnico » of Viamão, Rio Grande do Sul (Brazil). In Europe,

the first plant is a biennial and the second a perennial, but in Brazil, neither stands longer than 8 or 9 months. At Viamaõ, *L. perenne* did not prove at all successful; *L. italicum* on the other hand did fairly well, giving 4 cuttings a year and producing 200 quintals and more per hectare.

From the results of these trials, the author gives the following approximate estimate (in *milreis* per hectare: 1 gold *milreis* = 2.832 *fr.* at par), of the cost of cultivating *L. italicum*, in Brazil.

EXPENSES.		
Ploughing . . . . .	36	<i>milreis</i>
Harrowing . . . . .	13	"
Fertilisers and manure (3 to 4 quintals of lime and of much-decomposed dung) . . . . .	361	"
Seed and sowing (40-50 <i>lirs</i> per hectare). . . . .	67 5	"
Cutting (the 3 first crops, the last is grazed) . . . . .	18	"
Transport . . . . .	27	"
Sundries . . . . .	21 7	"
Total expenses . . . . .	547 2	<i>milreis</i>

RECEIPTS		
203.6 quintals of green forage at 3 <i>milreis</i> per quintal . . . . .	790.8	<i>milreis</i>

42 - Cultivation of *Phalaris bulbosa* in Uruguay (1). — PUIG Y NATTINO, J., in *Re-pública oriental del Uruguay, Ministerio de Industrias, Inspección nacional de Ganadería y Agricultura, Boletín No. 40*, 32 pp., figs. 6. Montevideo, 1921

In 1917, the author, formerly Head of the Agricultural Laboratory of the National Service of Inspection of Stock-Breeding and Agriculture, began a series of experiments in growing *Phalaris bulbosa* (Toowoomba Canary Grass), which he has continued every year since that date. In this paper, he gives a detailed account of his work and also reproduces the letters of agriculturists in different parts of Uruguay who have also tried cultivating this forage plant and describe its various qualities — high yield (2 to 5 cuttings per annum), rapid growth, hardiness, drought resistance, etc.

A series of Tables is appended, giving the meteorological data — height attained by the plants at different ages (20 days after cutting, 20 to 24 cm., in some cases, in others, 50 to 84 cm.; at the time of flowering, 90 to 130 cm.) — the water consumed during growth at the various stages of development (from 19.1 % to 34.85 % of dry matter, about 20 % in the majority of cases) — the yield at each cutting, and the total yield for the three years of the experiment (minimum = 31.8 quintals of grass per hectare in one cutting per year; maximum 641.7 quintals of grass per hectare in 5 cuttings per year; generally from 200 to 300 quintals a year) — the average composition of the grass (means of 5 analyses; water 80 %; protein 2.13 %; ash 3.12 %; fats 0.77 %; crude fibre 4.38 %; nitrogen-free extracts 8.60 %; starch value 10.04; nutritive ratio 1: 3.4) and dry matter ratio as compared with the chief forage crops.

43 - *Phragmites communis* as a Cattle Feed in Germany. — See No. 78 of this Review.

44 - Lucerne in North Africa. — TRABUT, in *Bulletin agricole de l'Algérie, Tunisie, Maroc*, Year 27, No. 8-9, pp. 129-131. Algiers, August-September, 1921. \*

The various authors who have studied the flora of N. Africa have stated that *Medicago sativa* is a wild growth.

POIRET also mentions *M. falcata* as occurring in Barbary, but it has since only been found in Morocco. It is possible that this author, who has chiefly studied plants in the Province of Constantine, has mistaken for *M. falcata* a *Medicago* with yellow flowers which afterwards received the name of *M. tunetana* Murbeck, 1897.

In 1873, URBAN, in his monograph on the genus, described the Algerian type, which is chiefly distinguished by its glandiform fruits, under the name of *M. getula*. In 1897, MURBECK recorded the *vulgaris* variety of *M. sativa*, but only as being cultivated here and there, but he mentions the variety *getula* Urban as occurring wild and describes the sub-species *M. tunetana* which is distinguished by its shorter, more rounded inflorescence, its pedicels becoming curved and bending back after the flower is withered, the more glandiform calyx, yellow, larger corolla, and glandiform fruits with 4.5 to 5.5 coils in the spiral, and a central orifice that is not easily distinguished.

MURBECK's statement is quite correct: *Medicago sativa vulgaris* is only to be found cultivated, or sometimes in process of becoming naturalised.

The wild lucerne, which is very common on the high plains and in the mountainous region of the East, is closely related to *M. getula* Urban, of which *M. tunetana* is a variety. This *Medicago* often grows on tufa covered with a thin layer of soil; it has a peculiarity that appears to have escaped the notice of botanists: the dense tufts pass downwards into numerous, often very long, underground rhizomes.

This character has never been observed in cultivated *Medicago sativa*.

The author has grown *M. getula* for several years at the Algiers Botanic Station, where it propagated itself by means of its rhizomes which formed an extensive matted growth. When raised from seed from the high plains of Numidia and from the mountains, this species proved to have fixed characters, only showing variation in the colour of its flowers, which were blue, pink, yellow and also white. Even in good soil, it did not grow well, and no large forage crop would be obtained from it.

In looking for the origin of *Medicago sativa*, the author came across references to *M. cancellata* M. B., *M. prostrata* Jacq., *M. Coerulea* Ledeb *M. Contorta* Gilib, etc. as varieties growing wild in S. Russia and Western Asia which are very nearly akin to, if not identical with *M. getula* and *M. tunetana* from North Africa and raises the question whether it is really a wild growth at all. Probably it is a case of a combination of two wild forms, such as usually occurs with most cultivated plants? If this is the explanation, he thinks that *M. falcata* is certainly concerned, for its characters are

seen in many of the plants composing the best lucerne crops, and there is a whole series of half-wild forms connecting *Medicago sativa* with *M. falcata* for which reason many authors include them both in the same species.

For the present the author is of opinion, that the name *M. getula* should be reserved for wild *Medicago*, and the name *M. sativa* used solely for the cultivated forms.

*M. tuncetana* Murb. is to be distinguished as a secondary form and is the most distant from the *sativa* type.

In the *Flore de France*, ROUY connects *Medicago getula* with *M. glomerata* Balb., and describes an *M. cirtensis* Rouy which is simply *M. tuncetana*. MURBECK'S name, seeing it has two years' priority, should be retained.

In the district of Sétif, where lucerne is cultivated, hybridisation certainly takes place, as seems to be shown by the observations of M. W. OLIVER, of the Bureau of Plant Industry, Washington, for in a sowing from Sétif he was able to distinguish fifty kinds of lucerne seed.

These derivatives of *M. getula* may become useful on account of their cold resistance, as the author saw *M. tuncetana* growing at an altitude of 2000 m. in the Aurès massif in Chelia. Their power of spreading by means of rhizomes may also render these lucernes valuable for making permanent pastures on poor, shallow soils.

The large number of varieties of cultivated lucerne grown in the Algiers Botanic Gardens have made it possible to discover many fixed forms with quite different characters. At the present time, the efforts of the breeder are devoted to the selection of a Peru lucerne that shoots much earlier than the so-called Provence variety. It also goes on growing so much later into the autumn, that a permanent crop could probably be obtained in the coast districts.

For the elevated plains where the winter is more severe, hybrids between *Medicago getula* and cultivated lucerne, preferably Peru lucerne, are the most suitable.

It is necessary that crosses should be made between *Medicago getula* and *Medicago falcata* for the purpose of obtaining a hardy lucerne suited to the climate of the High Plateaux.

RYF, at Sétif, has already made an attempt at acclimatising a variety of lucerne capable of thriving without irrigation. The seed collected in the neighbourhood came, at least to some extent, from hybrids between introduced lucerne and the wild variety which grows plentifully in the district. In order, however, to obtain any results of practical utility, it would be necessary to study the numerous derived forms, to isolate them and breed them systematically, a work which can only be done on the spot and by an expert in genetics.

45 - **Cultivation of Sulla in Eritrea.** -- Ministero delle Colonie, Ufficio Affari Economici, *Bollettino di Informazioni*, Vol. IX, Nos. 5-6, p. 278. Rome, May-June, 1921.

Sulla was introduced into the Colony of Eritrea by Baron FRANCHETTI'S special Colonising Mission (June 1890 - February 1895), but the first at-

tempts at cultivating this plant on the plateau were very unsuccessful. Now however it is grown without difficulty, for it shoots well, is resistant to the most prolonged drought, and yields an abundant supply of excellent forage. The Italian colonists sow sulla both on the plateau, and also half-way up the slopes. Owing to its deep, tenacious roots, this plant is able to bind the soil thus preventing the formation of the deep cracks that otherwise result from the heavy rains and the soil evaporation.

- 46 - *Atriplex semibaccata*, a Good Forage Plant for Chile (1). — SARABIA, A. G. (Agrónomo regional de la 1<sup>ra</sup> zona), in *Boletín de la Sociedad agrícola del Norte*, Vol. II, No. 5, pp. 81-82. La Serena, May 1921.

According to the author, *Atriplex semibaccata* resists the dryness of the soil better than any of the other forage plants introduced into Chile, and therefore is spreading rapidly through the country. On farms where it is grown, double the number of cattle can be kept per unit surface area of natural pasture. A meadow of *A. semibaccata* stands from 6 to 10 years in North Chile. Its drought resistance is due to its long, well developed roots. It bears seed from the 1<sup>st</sup> or 2<sup>nd</sup> year of planting (as much as 1 kg. per bush may be obtained).

This Chenopodiaceae (known popularly as "pasto salado") requires damp air, and only thrives on the coast zone, on a belt 30 to 40 kilometres in width. It is susceptible to frost, but is not exacting as to soil, although naturally the finest crops are grown on the most fertile land.

*A. semibaccata* is a forage eaten by all stock, with the exception of horses; mules and donkeys will take it, and cattle, sheep and goats consume it with avidity.

#### FIBRE CROPS

- 48 - Cotton Cultivation in Korea. — *The Textile Recorder*, Vol. XXXIX, No. 461, p. 74. Manchester, November 15, 1921.

According to the statistics published in a recent number of the Official Gazette of the Government General of Korea, the growth of cotton plants up to the end of June this year, both before and after budding, has on the whole been good, owing to favourable weather. The area in the 10 provinces under cultivation amounted to 263 802 acres of Upland cotton, and 98 748 acres of native cotton, showing a total increase of 14 092 acres compared with the 1920 figures.

From experiments made on Government model farms it has been reported that the American variety known as "King's Improved" (*Gossypium herbaceum*) is the best adapted to the south of Korea and yields better results in spinning than the native variety. The area devoted to the cultivation of the foreign variety has steadily increased from 15 791 acres in 1912 to 263 802 acres in 1921, while the native variety has shown a small decline from 109 382 acres to 98 748 acres.

During 1920 there was exported 63 046 lb. of cotton in the seed, val-

(1) See R. July 1921, No. 705; R. August 1921, No. 807. (Ed.)

ued at 2466 yen (1 yen = 2s at par), and 8 764 871 lb. of ginned cotton, valued at 6 000 786 yen.

Practically the entire amount was exported to Japan. Although the industry is developing, Korea is still dependent on supplies from abroad for the greater part of her cotton goods.

49 - **The Past and Future of Olive-Growing in Libya.** — DE CILLIS E., in *Ministero delle Colonie, Ufficio Affari Economici, Bollettino di Informazioni*, Vol IX, Nos. 5-6, pp. 271-275 Rome, May-June 1921.

PLANTS  
YIELDING OILS  
DYES TANNINS  
ETC.

Libya is a country eminently suited to the cultivation of the olive, and formerly this industry flourished side by side with sheep-rearing and cereal growing, as is proved by the vestiges of Roman olive-presses that are to be seen on an area of thousands of hectares in the hinterland of Homs (the ancient *Leptis Magna*); Cyrenaica is in equally fortunate circumstances as regards the cultivation of this valuable tree.

Along the Tripolitan coast zone, stretch numerous oases growing some 142 000 olive trees; in the oases of Tripoli alone (Menscia, Sahel, Tagiura, Gurgi and Gargaresc), there are 18 907 young trees and 39 045 adult, giving a total of 57 952. There are 40 000 olive-trees in the "genanât" (dry gardens) of the district of Homs; 130 000 in the splendid "gabe" (specialised olive gardens), of Msellata; 96 000 in Gârian; 81 500 at Jêfrem; 80 000 at Fassato; 35 000 at Nahût, 7000 at Orfella. The number of olive trees in the whole of Tripolitania may be estimated at over 600 000. At Homs and Msellata, where scientific dry-farming methods are adopted a more or less abundant crop is obtained annually, even when the rainfall has been very scanty. In good years, enough olives are grown at Msellata alone to supply all Libya. In 1918, 12 000 hectolitres of oil were produced in the oases of Tripoli, and it is calculated that the 1920 output will reach the same figure.

In Cyrenaica, there are some olive-trees in the irrigated gardens of Bengasi and Derna and in the dry gardens of el-Merg, there are also a few scattered specimens in the gardens of the interior, at Messa, Es, Ain-Mara and el-Gubba, but in all the woods of the plateau, wild olive trees are to be found. On the terraces of Cyrene (especially on the slopes of the "uidian" where traces of the stepped structures made by the ancient Greek colonists are clearly visible) and on the plateau dominating Derna, are still to be seen olive trees that have been allowed to run wild and receive no care from the natives. The passing Arabs gather the fruit and take it to the 2 oil-factories set up by Italians at Derna where the oil made is equal in quality to the finest product of Southern Italy.

The whole of North Libya is adapted to olive cultivation, with the exception of the dune zone, which is, however, of very limited extent. Even this does not represent the whole of the olive-growing region, the trees thrive and bear fruit in the "uidian" of the pre-desert district, as well as in Wady Soffegin, at Zauia Msus in Tripolitania, and in Wady Msus in Cyrenaica. At the gates of the Libyan Desert, in the desolate region of Balte, in the midst of the Wady Ramba (torrent of sand), the author

has found an olive-tree marking the extreme southern limit of the species, 100 kilometers from the coast

If we estimate the superficial area of N. Libya at 79 000 sq. kilometers there remain, after subtracting the waste ground (reckoning this at  $\frac{1}{3}$ , which is however a rather high figure), 53 000 sq. kilometers on which the olive-tree thrives. By adopting dry-farming methods, 1 million hectares could be planted with 20 trees per hectare; this would give 20 000 000 trees, enough to supply the whole of Libya.

That the cultivation of olive-trees is both profitable and remunerative is shown by the author who gives a brief account of the history of the Sialine land of Tunisia in the district of Sfax (the latter, taking it as a whole, is the region least suited to the olive). There are 160 000 hectares of Sialine land (viz. property taken away from the family of Siala and confiscated by the Bey of Tunis), which have been turned into olive-gardens under the "mougharsa" system of tenure; this is the system obtaining among the Arabs and it is much liked by the natives. According to the contract, the owner hands over the land to the agriculturist who binds himself to lay out a garden, or make a "gaba" (plantation of trees). The agriculturist provides all the necessary capital and labour, or else borrows it from the land owner. He enjoys all the return from the land, without paying any rent, until the trees begin to bear (which in the case of olives is generally 12 years). Then the land is divided into two equal portions, one half, which has been much improved, goes to the owner, and the other becomes the absolute property of the agriculturist who has planted it

In 1893, the French Government put up the Sialine land for sale, in lots, offering it to French citizens at 10 francs per hectare on the condition of its being planted with olive-trees. The land was bought and at once made over to natives under the "mougharsa" contract. Thus, between 1893 and 1907, 2 350 000 olive-trees were planted in the Sfax district; at the present time, their number has increased to 3 500 000. From the figures carefully obtained on the spot by the author, it would appear that at pre-War rates, the expenses per hectare of olive-gardens amounted in 10 years to 198.90 lire; each tree has therefore cost 11.56 lire and in 20 years (when the olive-trees are in full bearing) will have cost 18.53 lire, not counting any return obtained in the meantime. The average value of each tree with the ground it occupies is then reckoned at 50 lire, that is to say, at 3 times the amount expended. On adding to the price of the land (10 lire per hectare), double that sum for making wells, building houses, general expenses, interest for 20 years, etc., we get, with an outlay of 30 lire per hectare, the sum of 430 lire for the 95 hectares, this represents a gain of 1433 % for the landowner. The native by expending 135.50 lire gains 317 %. Finally, at the 20th year, he obtains a net return of 4.12 lire per tree, namely about 8 % of the value of the land.

In Libya, there are however no Sialine lands. All the land is in the hands of the natives, either in the form of private property ("mulch") or of collective property ("mètruke") This might appear a great objec-

tion to the "mougharsa" contract, but it is not, for the clauses are simply reversed, the native taking the place of the owner, and the French colonist, who possesses the capital necessary for planting, becoming the "mougharisa". The Libyan landowners or the Arab tribe would be perfectly competent and willing to assume the duties devolving upon them, and examples of such an arrangement are not wanting in either Tripolitania or Cyrenaica. By this means (with pre-War prices), the colonist would be sure, not only of obtaining compound interest, but also of seeing his capital trebled in 20 years.

50 - **Notes on Indigo<sup>(1)</sup>, Effect of Phosphate Manures and General Conditions Affecting the Yield and Quality of Seed in India** (1). — DAVIS, W. A. (Indigo Research Chemist to Government of India) — I. Effect of Superphosphate Manuring on the Yield and Quality of the Indigo Plant. — II. Effect of Manuring with Superphosphate and Sannai (*Crotalaria juncea*), on the Yield of Crops on Indigo Planters' Estates in Bihar, especially on Rabi Crops in Season 1918-19 — III. Conditions affecting the Quality of the Java Indigo Plant (Leaf Yield and Richness of the Leaf in Indigotin) — IV. ARKINS, W. R. G. (Indigo Botanist). Note on the Deterioration of Indigo Seed during Storing, in *Agricultural Research Institute, Pusa, India Publication*, No. 4, pp. 19 + 2 tables, 1918; No. 6, pp. 30, 1920; No. 7, pp. 33 + 9 tables, 1920, and No. 10, pp. 9 + 7 tables, 1921. Calcutta

I-II. — EFFECT OF SUPERPHOSPHATE MANURING ON INDIGO PLANTS. — That the principal factor in determining high yields of indigo (not merely of green plants per acre but the actual produce forthcoming) lies in the nature of the available foodstuff *in the soil* at the time the plant is grown appears clear from the results here reported from India.

A Table gives the yield of plant per acre, the weight of cake indigo obtained per acre, the yield of cake indigo per 100 maunds of plant, and the weight of green plants required to produce 1 maund of cake indigo (1 maund = 82.27 lb.) under different conditions of manurial treatment.

The following points stand out very clearly as regards the effect of conditions of growth on the quality and yield of produce:—

1) The plants grown on land treated with superphosphate and sannai (*Crotalaria juncea*) in June, were of a very much better quality than those grown on more fertile land which had received no manure, but was left fallow for 12 months — as shown by the yield per 100 maunds of plant being 13 seers 15 chataks (1 seer = 2.2 lb., 1 chatak = 2 oz.) as against 10 seers, 14 chataks. Thus, although the actual yield of plants per acre was slightly less (94 maunds, 6 chataks as against 95 maunds, 12 chataks), the actual produce of indigo per acre was considerably higher (13 seers, 2 chataks as against 10 seers, 5 chataks). By the first week in July not only was the actual yield of green plants per acre far higher in the case of the super-treated land but the quality was also far superior, so that the yield of cake indigo reached the phenomenal value of 32 seers, 4 chataks per acre for a single cutting. This value is from 2 to 3 times

(1) See R. Oct. 1921, No 1057 and No 101 of this *Revue*. (Ed)

greater than that obtained from plants grown on "seeded" land (*i. e.* land where refuse from steeping vats has been applied).

The figures given for the average yield of cake indigo per acre are at variance with the idea frequently held by planters that the low yields of indigo recently obtained on most estates are due to deterioration of the Java indigo plant. It is now evident that enormous yields of indigo can be obtained even in a year of unfavourable climatic conditions and with the existing Java plant provided that soil conditions are favourable. The author estimates that the majority of lands in Bihar can by steady manuring for a few years be made to yield 20 to 30 seers of indigo per acre in the course of two harvests.

From the results at Moniara it appears that a combination of green-manuring with sannai and superphosphate is an ideal one to ensure not only a high yield of plant but also high quality.

These results were confirmed in 1919 on various estates and in Bihar the treatment with super and sannai more than doubled the yield of green plant (141  $\frac{1}{2}$  maunds per bigha) (1 bigha = 0.87 acre). The yield of cake indigo per bigha was also double on the manured land than on the rest of the cultivation.

**EFFECT OF MANURIAL TREATMENT WITH SUPERPHOSPHATE ON THE YIELD OF RABI CROPS (*i. e.* SPRING CROPS).** — Some extraordinary increases have been reported from Champaran (Bengal) by the use of superphosphate alone and very poor lands which as a general rule failed to yield good crops, have given as much as 15 to 24 maunds of oats per acre. The application of superphosphate in conjunction with a green crop such as *Crotalaria juncea*, etc. has also brought about considerable increases. The soils in this case are very light and it is a remarkable fact that it is in these very light, well drained soils where aeration is most perfect that superphosphate has given the most striking results. In certain parts of India *e. g.* the Muzafferpur, Darbhanga and Monghyr Districts, there is a very marked deficiency of organic matter; hence the necessity for the addition of green manure. In such soils of which the Pusa soils may be taken as representative, superphosphate applied alone produces only about half the increase of crop which is obtained by the combination of green manure and super-phosphate.

To ascertain the actual manurial requirements of each estate it will be necessary for planters to make trials themselves with super alone or combined with organic manure for indigo and rabi crops. Results will be reported next year. The considerable increases of both indigo and cereal crops shown to be possible by the past trials makes the future position of natural indigo very hopeful.

**III. — CONDITIONS AFFECTING THE QUALITY OF THE JAVA INDIGO PLANT.** — Trials have been made at Pusa to ascertain the effect of growing a cover crop (such as wheat) with indigo, on the quality and yield of the indigo crop. Results already obtained throw considerable light on the conditions which determine high quality in the plant and the relationship existing between soil conditions on the one hand, and richness of the plant in indigotin on the other.

The indigo which follows the wheat grew slowly at first, probably owing to the removal of moisture from the soil by the wheat crop ; but after the monsoon broke it was found to develop well and finally to give an exceptionally high quality plant with a high percentage of indigotin.

Data are given showing the yields and analyses of Java plants from the Punjab area in 1919, and the following figures show the comparison in quality of plants : B. 9 grown on one section with wheat as a cover crop and B. 16 indigo plants grown continuously ; — Total for season : Plants per acre : 114 maunds 8 seers compared with 106 maunds ; Possible yield of 60 % cake indigo, 28.97 seers and 13.90 seers respectively.

The percentage of indigotin in the leaf appears to be determined mainly by the amount of readily available nitrogen in the soil ; when this is high, the indigotin content of the plant is low, *e. g.* B. 9 has a decidedly lower value for nitrogen than most of the indigo soils in Bihar and B. 16 is unusually rich in nitrogen.

Trials have demonstrated that the essential conditions to ensure the good growth of high quality indigo plants in addition to the above mentioned points are :— *a*) a good supply of carbohydrates in the form of decomposable organic matter ; *b*) a good supply of soluble phosphate in the soil to stimulate favourable growth and activity of the nodule bacteria (See I and II). In the case of indigo the problem is to supply organic matter without at the same time increasing the readily available nitrogen. If organic manure is added, the author considers that the indigo should not be grown until the nitrogen has been reduced by taking out other crops, otherwise although a large crop of indigo may be obtained the indigotin produced will be low. Recommendations are made to grow indigo with a cover crop (wheat, mustard or flax, etc.) after manuring with *Crotalaria juncea* and super.

IV. — DETERIORATION OF INDIGO SEED DURING STORING. — Experiments have been made with a view to the discovery of the best method of storing Java seed. On testing the various samples after the rains the following germination capacities were obtained : — Seed treated with acid : closed bottle, 84 % ; open box nil. Untreated seed ; closed bottle 8 % without treatment, 90 % after treatment ; canvas bag, 74 % after treatment ; Buried in " bhoosa " 77 % after treatment, open box 60 % after treatment. Results showed that treated seed can only be kept over the rains in sealed vessels ; untreated seed can be kept in dry sacks with safety. The loss of about 15 % in germination capacity which the untreated sample stored in a sack appears to show represents a proportion of the unripe seeds in the sample.

An attempt was made to correlate the germination capacity and colour by taking 100 seeds at random and ascertaining the percentage of light and dark coloured seeds, also the number of each that germinated and the total germination, those only germinating within 2 days being included in the accompanying data. The usual treatment with acid was given and some seeds required repeated treatment ; these specially resistant seeds in most cases failed to germinate. — Hence the importance of a thorough

treatment with acid. The usual time of treatment is 20 to 30 minutes; but it should be varied according to temperature (the chemical reaction being approximately doubled by every increase of  $10^{\circ}$  C).

After observations made with reference to the shape, swelling of seed in water, weight and comparative rate of germination according to the colour of the seed, it appears fully established that the change in colour which the seeds undergo is a good indication of their condition, a marked change denoting a loss of vigour amounting in many cases to complete failure to germinate. Elongated seed seems to perish more rapidly than plump round seeds.

Among the samples examined, those of high seed weight were superior to those of low weight with respect to their retention of germinative vigour. Hence the importance of the seed being well matured before gathering.

It is suggested that planters should vary the usual time of acid treatment to find the best time for the given seed sample and temperature.

RESIN PLANTS**

- 51 - **Notes on Alternate Tapping of Hevea in Indo-China.** — GIRARD, E. (Administrateur Délégué des Plantations de Suzannah et An-Lôc, Ancien Président p. i., du Syndicat des Planteurs de Caoutchouc de l'Indochine), in *Bulletin des Caoutchoucs de l'Institut Colonial de Marseille*, No. 1, pp. 2-15. Marseilles, 1921.

Results obtained from a series of experiments covering a period of 6 to 7 years conducted in Indo-China with a view to ascertaining the most productive and the most economic form of tapping. It appears to be clearly advantageous to allow comparatively long intervals between the actual tappings.

Dealing first with the alternate month system, the following conclusions have been drawn from these experiments :— 1) That the decrease in yield varying according to the condition of the trees at the time alternate tapping commences, may be as much as 80 % during the first months (comparing each month separately) and about 50 % for the entire first year of alternation. This reduction in yield is, however, counterbalanced by the economy effected as regards manual labour, and the fact that the bark is always in fresh condition preparatory to tapping; — a point which is not habitually the case when the daily tapping system is adopted. The lack of manual labour is a serious question in certain districts and matters may evidently be rectified by adopting this alternate month system. If this method does not prove sufficient to meet the labour situation, it has been demonstrated as shown by interesting data referring to a long series of experiments, that 3 groups may be given to each gang, trees being tapped only once every third month; both in this case and the alternate month system, the weekly one-day rest can easily be allowed to the labourers and this is advantageous from the point of view of physical strength, choice of coolies, etc.

2) The decrease in yield observed during the first years is considerably less before the close of the second year when it may be estimated at only 15 to 20 %.

Apart from general experimentation over a wide area 5 plots of equal

(1) No I — Tapping 3 times per month at intervals of 10 days, and from Aug. 1919 onwards tapped every 3 months.

(2) No. II. — Control; tapping daily.

(3) Nos. III, IV, V — Tapping alternate weeks, twice a month (2 weeks between each), and from Aug. 1919 onwards, every other month.

superficies were planted with *Hevea* of similar origin and age and at regular intervals. The soil and treatment were identical in every case. The data in the annexed table show the results obtained; it is interesting to note also from the economical standpoint the number of workmen employed for tapping.

- 52 - **Possibility of Cultivating the Camphor Tree at Porto-Rico.** — LEGRAND, J. F., in *Revista de Agricultura de Puerto Rico*, Vol. VI, No. 6, pp. 7-8, fig. 1. San Juan, P. R., 1921.

The author mentions the presence of some fine camphor trees on the agricultural farm annexed to the University of Porto Rico. The perfect acclimatisation of the existing specimens proves that these valuable trees can be grown in the island. The author advises that they should be cultivated on a large scale, seeing that large profits could be realised by this means.

- 53 - **A New Method of Harvesting Coffee.** — DE AMARAL CASTRO, J., in *Chacaras e Quintas*, Vol. XXIV, No. 3, pp. 195-196. São Paulo, September 15, 1921.

The Author suggests that coffee should be harvested by shaking the shrubs and afterwards collecting the berries that fall to the ground. He considers this a better method than the one hitherto adopted, viz. passing the hands over the little branches and thus detaching the fruit, as it prevents any injury to the buds upon which the next crop depends and also economises labour. The fallen berries must be collected in 2 or 3 months, at the latest, that is to say, before there is any risk of their becoming spoilt.

- 54 - **The Santalaceae and Sandal-Wood: Distribution and Uses** (1). — GROUT, C., in *La Parfumerie Moderne*, Year XIV, No. 9, pp. 196-197. Lyons, September 1921.

The genus *Santalum* is the typical genus of the family of the Santalaceae which is characterised by a 3-5 lobed perianth, the same number of opposite stamens, and bilocular, longitudinally dehiscent anthers. The ovary is inferior, adherent and unilocular, with 2-5 ovules. The fruit is monospermous and surmounted by a persistent limb.

The family of the Santalaceae is represented in France by a single species, *Osyris alba*. This is a low-growing shrub that may attain the height of one metre and is found growing on the sandy, dry soils of the olive region where it is known by the name of "Rouvet". It has striated branches, persistent, pointed leaves with a single vein. Its flowers are dioecious, small, and yellowish; they are situated at the apex of the branches, the male flowers growing in clusters, while the female blossoms are solitary. The fruit is red and of the size of a pea.

Another species (*Osyris tenuifolium*), has thin leaves; it furnishes a wood that is very similar to the product of *Santalum album* (the sandal-

(1) See Jan. 1918, No. 2, p. 22. Production of Sandal-Wood Oil in Mysore, British India. (Ed.)

wood tree), and is an article of some commerce. It is exported chiefly from Zanzibar.

*Osyris tenuifolium* is a shrub or small tree, growing freely in the mountainous districts of East Africa. Its flowers, like those of *Os. album*, have free sepals crowning an inferior ovary. The fruits are drupes.

The sandal-wood of antiquity come from *Santalum album*. This is a small tree some ten metres in height, of very bushy habit. Its leaves are persistent, and it has small brownish flowers and reddish fruits. This plant is found in India, Malaysia, and China, at heights varying from 600 to 900 metres. The sap-wood is white, thick and soft, the heart-wood being of a brownish-yellow colour with bitter taste and a strong clinging smell. This wood is close-grained, very dense and difficult to split. The decorticated trunks of commerce have a very pleasant odour of musk, rose and lemon. They should contain little, if any, sap-wood, and are rich in essential oil. The heart-wood furnishes the lemon-coloured, or yellow sandal-wood whereas the sap-wood is the white sandal-wood.

The sandal-wood oil of India comes only from *Santalum myrtifolium*, *S. insulare*, *S. Homei*, *S. Yasi*, shrubs growing in India or the Sunda Archipelago.

*Santalum Pressianum* which grows in South Australia, where it is known under the name of Quandong, furnishes a dark-brown, very heavy wood with a fragrant odour resembling that of the rose. It yield 5 % of cherry-red, viscous liquid and produces edible fruit.

*Santalum cygnorum*, or *Fusanus spicatus*, is found in West Australia, and *Santalum Yasi* in the Viti Islands.

A wood very similar to that of *Santalum album* comes from the Ha-soranto of Madagascar.

The red sandal-wood tree of India is *Pterocarpus indicus* which is a member of the Papilionaceae (Leguminosae). It is also found in Burma, Annam, Cochin-China and the Andaman Isles, and is a tree of considerable growth, but no great height (10 m. at the most). The wood is red, very hard and heavy (average density 1.05); it furnishes an astringent colouring matter, now little used.

The red sandal-wood of Africa comes from *Pterocarpus santalinoides*, *angolenis*, or *tinctorius*. It is coarser-grained, but more brilliant in colour than the Indian product, and is used in dyeing.

The red wood of Kodar, or Calliatour wood, is the product of *Pterocarpus santalinus*. This tree is found in Southern India and conveyed to the Coromandel coast. The alburnum is thin and light in colour, the duramen is a more or less dark-red, often almost black. It was formerly much prized for dyeing. Now it is used for carving, the idols of the natives being fashioned from the wood of the roots.

The Padouk of Burma, is *Pterocarpus macrocarpus*, its wood is hard, and varies in colour from a light yellowish-red to a dark brick-red.

The red wood of the Andaman Isles comes from *Pterocarpus dalbergioides*. It is very resistant and durable; its colour ranges from dark-red to brown.

The Kino *Pterocarpus* (*Pterocarpus marsupium*) is the source of the gum called Kino. The tree is found in Southern India and Ceylon. The colour of the wood varies from yellow to a brownish grey ; darker coloured bands run across the trunk of the tree. The wood is very hard and durable.

*Pterocarpus Michelei* growing in Argentina, (Iba-ra du Chaco), differ from the other species in furnishing only a somewhat light wood that does not last long.

*Pterocarpus cambodianus* (Dom Khtnongen-Kmer), is found in Cambodia. Its wood is reddish-brown and rather heavy.

The red mahogany of the Congo is *Pterocarpus erinaceus* ; this tree is said to produce the Kino of Africa and Gambia and is found in tropical Africa. It has a hard wood with twisted fibres.

The Gabon Padouk is *Pterocarpus Soyauxii*. Its alburnum is rose-coloured and thick. The duramen is semi-hard and of a coral-red with darker veins ; it becomes very brown on exposure to the air. This wood is used in dyeing.

The red sandal-wood of the Antilles, or soft Coral wood, is furnished by two species of tree ; *Pterocarpus draco* and *Pterocarpus gummifer*, it is lighter and less dark in colour than the ordinary red sandal-wood.

The hardest woods of the various species of *Pterocarpus* offer an extraordinary amount of resistance to the attacks of insects, especially to those of termites. It is this very quality, in conjunction with its pleasant smell, that has caused the sandal wood of *Santalum album* to be highly prized from the most remote antiquity. It is even spoken of in ancient Chinese and Sanskrit books. Seventeen hundred years before the Christian era, the Egyptians sent to Yemen for sandal-wood. The Buddhists used it for making religious statues and for the decoration of their temples ; the woods of different species of *Pterocarpus* are still sometimes employed for similar purposes.

From ancient times until our own days, several authors have written about sandal-wood. In the XV<sup>th</sup> century, one of them described three kinds, a white, a yellow, and a red. Another, writing in 1511, stated that the white and the yellow sandal-woods came from Malabar and were 10 times more valuable than the red variety.

Sandal-wood oil has only comparatively recently been extracted and studied. Probably however it has been known in Ceylon since the IX<sup>th</sup> century and used in embalming the bodies of important persons.

At the present time the Hindoos and Chinese still use sandal wood for burning at religious ceremonies, or rites connected with the worship of the dead and a large quantity of the Indian product is thus employed.

Sandal-wood is also much in request for carving, the manufacture of frames, boxes, coffers inlaid with ivory and for coffins. It is one of the four sudorific woods (the others being sassafras, China root and guaiacum).

In South India, *Santalum album* chiefly grows at an altitude of 2000 or 3000 ft. in fine soil mixed with gravel or in red clay, but these soils must be very well drained and aerated. The tree will grow quite well

at lower altitudes, though its essential oil content gradually decreases; at 700 ft. the trees are still vigorous, but the wood has no smell.

On fairly fertile soil, where the growth of the tree is slow, the wood is more scented than on rich soil which stimulates its development. Owing however to the greater size of the trees, it is possible to obtain more essential oil per acre in the second case than in the first.

In order for *Santalum album* to grow satisfactorily the ground must be slightly shaded by bushes and the climate fairly damp.

This tree flourished in hedges, or thinly growing forests. In fact, it will only grow in the neighbourhood of other trees or shrubs, which has caused it to be regarded as a parasite.

*Santalum album* can be exploited as soon as the scented portion of the wood is well developed. This occurs when the tree has a girth of 60 cm. to 1 m, and is between 40 and 50 years old. From this time, the tree may be expected to increase in girth 20 cm in 10 years.

Live-stock and game do much damage to forests of *S. album* by browsing on its leaves. These animals however also crop the grass thereby diminishing the danger of fires which are of frequent occurrence. Thefts of wood are very common; the natives cut the trees before they are sold, in order to find out the perfume content of the wood.

*Santalum album* is reproduced from its fruits; as it bears a liberal supply of the latter, there are always enough for the purpose, in spite of their being much sought after by birds, especially crows. There can be no question of propagation from shoots; for the roots are as much an article of commerce as the aerial woods. The seedlings are often suffocated by grass or climbing plants.

In India, most of the sandal-wood is produced in the province of Mysore, where there is a factory which possesses the sole right of distilling all the wood of the Province and is able to make purchases of wood in other centres.

*Santalum album* is beginning to be exploited in Tonkin, in the Province of Quang-Yen.

*Santalum cygnorum* from Western Australia, furnishes the "Swan River Santal Wood" that is put on the market at Singapore and applied to the same uses as the wood of *Sant. album*.

The Hasoranto of Madagascar (*Santalina madagascariensis*, belonging to the family of the Rubiaceae), produces an essential oil of good quality.

Sandal-wood oil is obtained from these woods by distillation. The yield is very variable, ranging from 1.5 to 5 %. The oil is of a more, or less light shade of yellow, its smell is faint, but clinging, resembling the scent of the rose; it has a disagreeable pungent flavour.

In this essential oil have been found: ethers; two levogyric alcohols (santalols), having the formula  $C_{15}H_{25}OH$ ; one aldehyde (santalal), with the formula  $C_{15}H_{34}O$ ; one carbohydrate (santalene) boiling at  $252^{\circ}C.$  or  $252.5^{\circ}C.$ ; another santalene boiling at  $261^{\circ}C.$  or  $262^{\circ}C.$ ; a carbohydrate boiling at  $130^{\circ}C.$  or  $140^{\circ}C.$ ; santalic acid an oxygenated product

to which is due the special smell of the essence and boiling at  $210^{\circ}\text{C}$  or  $220^{\circ}\text{C}$ ., (formula  $\text{C}_{15}\text{H}_{24}\text{O}_2$ ).

As santalols ought to make up 94 % of the essential oil, it is easy to detect any adulteration by determining the amount of these substances; should the santalol content sink below 90 %, the oil is no longer pure, but no fraud need be suspected if the percentage is above this figure.

The essential oil of the West Indies is prepared from certain Rutaceae (*Amyris balsamifera* and others), growing in Venezuela and tropical America. It has a far less delicate scent than sandal wood oil. *Amyris balsamifera* is the balsam of Jamaica, where it is usually known as Rose Wood; it is the Candle Wood of Guadeloupe.

Sandal-wood, when dried and pounded, is one of the ingredients of sachet-powders. The essential oil is not only used in perfumery, but also in medicine.

**55 - Clove Oil from Clove Stems (*Eugenia Cariophyllata*) in the Islands of Zanzibar and Pemba.** -- GADRE, S. T. (Industrial Chemist to Government, United Provinces, Cawnpore) in *Journal of Indian Industries and Labour*, Vol. I, Pt. 1, pp. 41-47. Calcutta, Feb 1921

It is estimated that there are in the Islands of Zanzibar and Pemba about 52 000 acres under clove (*Eugenia Cariophyllata*) cultivation, and about 4 700 000 trees in bearing; the plantations are chiefly owned by Arabs, and a few by Indians. The average output of the African cloves has been about 14 000 000 lb. a year but in 1918-19 the yield is reported as nearly 29 000 000 lb. The average yield per annum from a plantation of about 3 000 trees about 60 years old under European management is estimated to be 8 lb. per tree; 98 trees are planted to the acre.

The true cloves of commerce are the dried flower buds but the stems which primarily were known to contain a fairly large amount of brown dyestuff have since been found to contain an essential oil resembling that obtained from the true cloves. A sample obtained from a Zanzibar firm was found to yield about 3 % of this oil, and to contain about 80 % eugenol. These results indicated a possibility that the distillation of these stems might be successfully practised in India on a commercial scale, and a consignment was delivered to Cawnpore for experimentation.

The stems were soaked in water over-night and the wet, swollen stems were then distilled with steam at a good pressure. A description is given of the plant and process employed.

The freshly distilled oil had a pale yellow colour, which deepened on exposure to air and light and turned distinctly brown when heated in a water bath. In aroma and quality it was equal to the best English distilled clove oil. It had an irritating action on the mucous membrane and left a slight burning sensation on the skin. The free eugenol in the oil was estimated by the volumetric method of VARLEY and BOLSING and the amount existing in an uncombined state in the oil was found to be 69.86 %, and the total eugenol usually from 85 to 90 % (UMNEY'S method), but up to 95 %, has been found.

Data are given for the calculation of the cost of production of the oil. The figures refer to actual costs incurred during the experiments described above. Tables are given comparing the properties of the oil made from clove stems at the Cawnpore Laboratory with those of different samples of clove oil as quoted by PARRY (*Chemistry of Essential Oils*). The former is apparently richer in eugenol and consequently higher in specific gravity than an average sample of true clove oil, and the difference between the oil obtained from the two sources should therefore be only in quantity and not in quality. True cloves are said to yield up to 20 %, compared with stems up to 6 %. If however the price of clove oil were fixed by the eugenol content, the oil obtained from stems as here described should certainly fetch a higher value than an average sample of clove oil in the market.

From the reports made by a leading and influential firm in India and from the author's own experiments, it is considered advisable to use these stems as the main source of supply of the clove oil of trade, thus leaving the true cloves to meet other needs for which they are greatly in demand. As regards the supply of clove stems, it should be possible to obtain them with proper organisation, for a comparatively cheap price and in sufficient quantities.

- 56 - **Notes on Virginian and Turkish Tobaccos: Modes of Production, Supply and Demand with Special Reference to Rhodesia and Other Provinces of South Africa.** — I. TAYLOR, H. W., The Tobacco Industry, Tobacco Growing Countries etc., in *The South African Journal of Industries*, Vol. IV, No. 5, pp. 465-472, Pretoria, June 1921. — II. IDEM, Seed Selection in Tobacco Culture, *Ibidem*, Vol. IV, No. 6, pp. 563-571, pl. 3 July 1921. — III. IDEM, The Culture of Virginian Tobacco, *Ibidem*, Vol. IV, No. 7, pp. 650-662, pl. 4 Aug. 1921. — IV. IDEM, The Curing of Tobacco, *Ibidem*, Vol. IV, No. 8, pp. 727-732 Sept. 1921. — V. IDEM, The Culture of Turkish Tobacco, *Ibidem*, Vol. IV, No. 9, pp. 794-799, pl. 1 Oct. 1921, and in *Bulletin No. 373, Department of Agriculture, Salisbury, Rhodesia*, pp. 1-10, figs. 7, Salisbury, Dec. 1920. — VI. HEMMERLÉ, J., La culture du Tabac en Rhodesia, in *Revue Agricole de l'Île de la Réunion*, Pt. 2, No. 5, pp. 172-177, Saint-Denis, May 1921.

The opening article gives a general survey of the distribution of tobacco areas throughout the world, but apart from the data relative to the production and consumption in the United States, the detailed description of areas suitable for tobacco production, including types and quality of tobacco produced, is confined to the South African Provinces. The succeeding articles relate entirely to South Africa and cover the whole field of tobacco production from the preparation of the seedbeds right through to the marketing of the cured leaf.

I. SOUTH AFRICA. — *Distributive areas.* — The total amount of commercial tobacco produced in Africa is probably not above 70 000 000 lb. at present. In the Union of S. Africa the production for 1919 was 14 183 000 lb. and in Rhodesia 1 467 612 lb. as compared with 620 171 lb., in 1918. The types of tobacco produced can be divided into four classes, *viz* Virginian (flue-cured) in Rhodesia; Turkish in the Western Provinces; Pipe Tobacco in Transvaal (Magaliesburg); and Cigar Tobacco in Natal.

Owing to the variable characteristics attached to each type of tobacco in each country, S. African tobacco should not be compared with that grown elsewhere on the basis of quality, which is a variable term. The author however here gives the principal characteristics of the several types produced in S. Africa : — The general methods of cultivation etc. are not given in this summary as they are already well known, but certain outstanding points have been selected.

I, III. VIRGINIA. — This varies so much in its natural characteristics that the leaf from each producing area is considered separately. A rainfall of 25 to 30 inches is sufficient for cultural purposes, provided it is properly distributed. In Rhodesia, the rainfall is ample and the annual distribution fairly uniform, thus rendering this area very suitable for tobacco growing (1).

*Varieties.* — Rhodesian Virginian tobacco is practically all flue cured and varies in colour from lemon-yellow to mahogany and dark brown. Only Hester, Goldfinder and South's are grown to any extent. The last variety originated under Rhodesian conditions and is especially suited to its local environment. In the Union the varieties recommended are as follows : For heavy or dark leaf : Improved Clarksville, Boyd, Genuine Pryor, Tennessee Red, Joiner, each to be grown on heavy well fertilised soil. For medium bright or light red leaf : Joiner, Yellow Pryor, Sterling, Hester, Bullion, Blue Pryor, White Burley each to be grown on sandy loam with moderate application of fertiliser or manure. For bright leaf : same varieties as for medium bright, to be grown on sandy loam or black turf soil with light applications of fertiliser or manure.

II, III. *Seedlings and seed selection.* — Notes with reference to seedlings and seed selection (II), apply equally to all types of tobacco. An E. or N. F. exposure is considered best, and windbreaks are advisable. At the Piet Retief Tobacco and Cotton Experiment Station a very effective shelter was made with maize stalks held in position by double strands of wire. Attention is drawn to the fact that a common mistake is often made in sowing too thickly. It is estimated that if properly cleaned and graded seed is used 1 oz. is sufficient for sowing 120 sq. yd. of seed bed. (1 oz. contains approximately 300 000 seeds). Cheesecloth has been found to be the most suitable covering for seed beds.

According to SCHERFFIUS (*Bull. No. 139. Kentucky Agricultural Expt. Stn.*), and TRABUT (*Bull. No. 17. Service Botanique, Gouvernement Général de l'Algérie*), only heavy and well developed seed will give good results. The fact that imported seed gives unsatisfactory results and that the yield from acclimatised seed is invariably larger and the leaf of better quality in every respect has been demonstrated conclusively by experiments conducted by the author in the Transvaal and also in Rhodesia.

The best soil for seedbeds is a deep, light, sandy loam. Black turf soil is somewhat too heavy, but the author has obtained excellent results

(1) See *R.* Oct. 1921, No. 941. (*Ed.*)

by applying sand to turf soil and thoroughly mixing together, the plants being ready for transplanting 60 days from the date of sowing.

III. *Soils and Fertilisers* (1). — In giving a full description of the soil-preparation before planting and fertilisers, it is stated that as a general rule, the best quality tobacco is produced on new lands, which contain a large amount of humus, particularly in the case of sandy soils which, if cultivated continuously, will not produce leaf of the best quality, regardless of the amount of fertilisers applied, apparently owing to the lack of humus.

As regards fertilisers, according to JURITZ (Study of the Agricultural Soils of the Cape Colony), many of the soils in the Cape Province are deficient in phosphoric oxide and similar conditions are said to exist in Transvaal (REINECKE, *Bull. No. 81. Union of South Africa, Dept. of Agriculture*) and in Rhodesia (BLACKSHAW, *Rhodesia Agricultural Journal*, Vol. VIII, No. 6). In the Union the results obtained at several Experiment Stations of the Tobacco and Cotton Division of the Department of Agriculture indicate that the following formula is well suited for most tobacco growing areas :— Nitrate of soda 160 lb., dried blood 200 lb., sulphate of potash, 200 lb., superphosphates (37 %), 320 lb. The whole is well mixed and applied to 1 acre, once in 4 years. A ratio recommended as most suitable is 2 ½ % phosphoric oxide to 1 % nitrogen and 1 ¼ % potash.

III. *Rotation of Crops* — Rye is recommended as a suitable crop for improving tobacco soils, and should be turned under just before the seed heads appear. On very light sandy soils leguminous crops can be used with advantage. It is considered that a green manure crop (2) should be grown and ploughed under once in 3 years in order to maintain the proper supply of humus in the soil.

III. *Transplanting* (3). — During October, November and December; if planted out later unsatisfactory results have been obtained. The method employed depends upon individual conditions, and where irrigation is not necessary, transplanting can be done on the level or on ridges. There is a tendency on the part of many growers to transplant before the seedlings are sufficiently large. Plants should be at least 3 inches in height and better stands are secured if allowed to remain until 4 to 5 inches high. If the tobacco is to be flue-cured, about 10 to 15 acres is transplanted at one time in order to secure sufficient leaf of uniform ripeness and even texture to fill a curing barn at each harvest.

A description follows of the cultivation, topping, suckering and ripening.

III. *Methods of harvesting*. — The whole plant method has been found the most economical for air, sun or fire curing, but for flue-curing the 'single leaf' method is generally used. For the first method the easiest way has been found to split the stalk to within about 4 in. of the ground,

(1) Experiments in Manuring See R. Nov. 1917, No. 1025. (Ed.)

(2) For green manuring, see R. April 1916, No. 387. (Ed.)

(3) For spacing of plants, see R. June 1917, No. 552. (Ed.)

bend the stalk slightly away from the operator and sever near the ground by a sloping cut. The plant is then placed astride a tobacco stick, which will carry from 6 to 10 plants, and is carted to the curing barns, etc.

In regard to the effect of the two methods of harvesting in respect to the weight of cured leaf obtained, GARNER (*Bull. No. 79. U. S. Dept. of Agriculture, Bureau of Plant Industry*) has shown conclusively that the loss of dry matter is greater when the whole plant is harvested, and the weight of the cured product is therefore less than when the tobacco is harvested by the single leaf method.

III.-VI. *Cost of Production and Profit per Acre.* — This naturally varies with labour conditions, etc., but the author found the cost of growing tobacco in the Transvaal (1916-17) was approximately 4d. per lb. with an average selling price of about 6d. per lb. In Rhodesia the cost of producing is about 9d. per lb., and the present selling price of a normal crop is about 1s 6d per lb. It is interesting to compare these figures with the existing cost and selling prices in the United States, *e. g.* the average cost in the Burley District of Kentucky is from 26 cents (1s 1d) to 30 cents (1s 3d) per lb. (*Western Tobacco Journal*, Vol. XLVII, No. 24). In the Dark Tobacco District of the same state the cost of production averaged 16 cents (8d) per lb. During 1919 Burley Tobacco sold at an average of 55.8 cents (2s 4d) per lb. (*Western Tobacco Journal*, Vol. XLVII, No. 3), and dark tobacco at an average price of 24 cents (1s) per lb. so that growers in each of these sections realised larger profits than the growers in South Africa.

I. V. TURKISH (1). — This tobacco in both the Western Province and Rhodesia has good colour, texture, body and burning qualities, but its flavour and aroma are not so pronounced as that produced in the Levant. Properly handled and matured however it would find a ready sale overseas for blending purposes.

As Turkish tobacco is sun-cured it is essential there should be practically no rainfall during the curing period. It is preferable if the rains cease about 1 month after transplanting. Generally speaking the climatic conditions in Matabeleland are more suitable than in Mashonaland where the rainfall is too heavy. In Rhodesia as a whole, the best results have been obtained on red clay loams derived from diorite or schist formations. Fertile sandy loams are also used and give good coloured tobacco with good combustibility (2) but lacking in body.

*Varieties.* — Plantings almost entirely confined to Kavalla, but in the Western Province, Soulook, Samsun, Dubek and Yaca are also grown.

II *Seedbeds, Preparation of Soil, etc.* — Similar methods to those adopted for Virginia tobacco.

*Location.* — Low lying soil is to be avoided as in these areas the crop is more liable to white rust (*Oidium tabaci*).

V. *Fertilisers and Manures.* — In Rhodesia these are unnecessary

(1) For Turkish Tobacco in Cape Province, see R. Jan. 1914, No. 32. (*Ed.*)

(2) For Investigations on Combustibility, see R. Aug. 1916, No. 868. (*Ed.*)

on red clay loams, and on sandy loams Kraal manure at the rate of 8 tons per acre or a commercial fertiliser (8-20-10 formula) is applied at the rate of 200 lb. per acre some time before the crop is transplanted.

V. *Transplanting, Cultivation.* — See *Virginian*

*Topping and Suckering.* — This type of tobacco is not topped and consequently it is not usually necessary to sucker the plants, and if the suckers appear when the plants are nearing maturity they should be removed.

*Priming.* — Small leaves at the base of the plant should be removed before the flower head appears.

V. *Harvesting and stringing.* — Single leaf method always employed.

*Wilting.* — This type of tobacco is allowed to remain in the wilting room until the leaf turns pale greenish yellow. Lack of proper supervision at this stage is annually the cause of considerable loss to growers especially in Southern Rhodesia. A description of a wilting room is given.

CURING (1). — A diagram indicates the various methods of curing employed and the types of tobacco cured by each method. The methods described include : a) air curing ; b) sun-curing ; c) fire curing and d) flue curing.

These methods do not differ from the generally recognised methods adopted. The barns used in Rhodesia in the two latter cases are also described in detail by HEMMERLÉ (VI).

Regardless of the method used in curing, tobacco can be either increased or decreased in value by the method of handling employed after the leaf is cured. The method recommended by TAYLOR is to bring the leaf into condition and place it in bulks or stacks about 6 ft in height, and a packing shed with a conditioning cellar should always be provided. Leaf which is harvested ripe but cures out with a greenish colour can be greatly increased in value by this method of handling as bulking removes the green colour and improves the aroma of the tobacco. When in proper condition for bulking or baling, the web of the leaf and lower half of the midrib, from tip to butt, should be supple, but the upper half of the midrib should be only slightly pliable.

ARBO-  
RICULTURE

58 - The "Pejibaye" (*Guilielma utilis*), Fruit with High Food Value in Costa Rica. — POPENHOE, W. (Office of Foreign Seed and Plant Introduction, United States Dept. of Agriculture) and JIMENEZ, O. in *Bulletin of the Pan-American Union*, Vol. LIII, No. 5, pp. 449-462, pl. 6. Washington, D. C., Nov. 1921.

Description of the "pejibaye" or "chontaduro" palm (*Guilielma utilis* Oerst = *Bactris utilis* Benth and Hook) which grows in Costa Rica, Panama and Northern South America. It is considered probable that the plant found in Venezuela, Colombia and Ecuador described botanically as *G. speciosa* and *B. gachipaes* is specifically identical with the Costa Rica *G. utilis*.

The authors recommend the introduction into tropical regions of this plant with a view to the extension of its culture so as to place it upon the substantial basis of a profitable commercial fruit and give details of the climate and soil to which it is adapted and the culture and varieties.

As regards the composition and food value of this fruit, the following figures show the chemical composition compared with other tropical fruits

	Water	Protein	Fat	Carbo- hydrates	Ash
	%	%	%	%	%
<i>Hymenoclea Courbaril</i> . . . . .	15.1	6.6	1.6	73.9	2.8
<i>Guilielma utilis</i> (boiled) . . . . .	48.8	2.8	0.7	40.9	0.8
Banana . . . . .	75.3	1.3	0.6	22.0	3.8
Avocado (Mexican) . . . . .	66.3	1.8	26.6	6.6	1.5
Avocado (Guatemalan) . . . . .	71.2	1.7	20.5	5.4	1.1
Avocado (West Indian). . . . .	78.6	1.6	0.8	9.0	0.8

An analysis of ripe, uncooked fruit gave the following result : Starch 26.90 % ; sugar 4 % ; fat 5.82 %.

The energy producing value, expressed in calories amounts to 1096 as compared with 1564 *H. Courbaril*, approximate average of 1000 avocado, and 459 banane. From the point of view of economic value, however, the "pejibaye" and the avocado occupy the first places, owing to the somewhat disagreeable odour and taste of the apparently highly nutritious *H. Courbaril* fruit.

The author describes the various ways in which the fruit is prepared for food. An experiment made by Doña AMPARO DE ZELEDÓN, based upon a suggestion of WERCKLE has given excellent results, viz. the paring of boiled fruits, removal of seed and oven drying for several hours. The water is extracted but the fruit retained its form, colour and general character. Six months later the dried fruit when boiled for half an hour regained the consistency and flavour of the boiled fresh "pejibaye".

In addition to the fleshy portion of the fruit, the hard white kernel which contains a large quantity of oil, is eaten ; the terminal bud can also be used as a vegetable but would necessitate the destruction of the palm and is therefore not worth consideration.

59 - Forestry in China. — Republic of China, Government Bureau of Economic Information Bulletin, S. 1, No. 11. Peking-Shanghai, May 6, 1921.

FORESTRY

China's progress in forestry during 1920 was significant. Developments in the year included: 1) the establishment of the Shantung Forestry Bureau; 2) the extension of afforestation to all the provinces; 3) the activities of the Provincial Forestry Station at Nanking; 4) the co-operation in the planting of trees by Kansu-Haichow, Peking-Hankow, and Tientsin-Pukow Railways; 5) the cultivation and distribution of plants; 6) the increased interest of district magistrates, agricultural associations, companies and individuals.

The number of plants produced during the year totalled about 130 000 000 and the cost of cultivating and planting them amounted to nearly \$250 000 (£ 1 = \$8.46). The institution of Arbor Day augured well for the future. The expansion of this practice of planting trees among all classes of the community must be included among last year's developments.

The Kiangsu Provincial Forestry Station was established in 1916. The yearly estimated expenditure was \$34 000, which was approved by the Provincial Assembly and appropriated by the Financial Commissioner of the province. The area under cultivation is 34 000 "mow" (1 mow =  $\frac{1}{6}$  acre) with 25 000 000 trees. There are also three gardens for the cultivation of shoots, occupying an area of 371 "mow", and three branch stations. Two more branch stations are under consideration. Students are trained at the Central station for a period of three years, and after this course they are sent to their districts to specialize in the industry. There are three afforestation stations and three gardens for the cultivation of plants in Shantung which occupy a total area of 2 000 "mow"; the annual expenditure appropriated by the Provincial Financial Commissioner is \$22 000.

The Government Railways which stand in need of a continuous supply of timber, are taking steps to plant trees for their own use. The Kansu-Haichow Railway has appropriated a sum of \$17 000 for forestry purposes. Three afforestation stations, each 120 "mow" in extent and the planting of 4 000 000 trees on each side of its track, are the result of its enterprise up to the present time. In the estimated expenditure of the Tientsin-Pukow Railway a sum of \$6 000 has been appropriated and trees already planted on this line number 850 000. Two gardens for the cultivation of plants have also been established. The Peking-Hankow Railway has assigned a large area for afforestation purposes in Honan.

In Central and North China there are 21 afforestation establishments occupying in all an area of 15 000 "mow" and having a total annual expenditure of \$106 000. The largest and most prosperous afforestation area is situated in the North of Kiangsu near Yenchow, where between 3 000 and 4 000 trees are grown every year. In addition specialist schools have been established in many provinces, notably in Anhwei, Chekiang, Hupeh, Szechwan, and Shansi. It has been estimated that 25 % of the

1 800 "hsiens" (departments) in China are now engaged in this work, which, it is hoped, will in due course transform many barren tracts into rich forests.

**60 - The Forests of the United States as a Source of Liquid Fuel Supply. —**

HAWLEY, R. C. (Yale University, New Haven, Conn., U. S. A.), in *The Journal of Industrial and Engineering Chemistry*, Vol. XIII, No. 11, pp. 1059-1060. New York City, Nov. 1, 1921.

The purpose of this paper is to present a concise statement showing the amount of wood available for conversion into liquid fuel which can be produced annually on the forest lands of the United States (Alaska and insular possessions excluded).

The forest area of the United States is as follows :

*Area and Growth of the Forests of the United States.*

Area forested Acres	Character	Present Growth Cub Ft	Possible Growth Cub Ft.
245,000,000	Second growth	5,995,000,000	14,700,000,000
81,000,000	Forest wasteland on which nothing can grow without reafforestation	Nil	4,860,000,000
137,000,000	Virgin forests.	Nil	8,220,000,000
<b>463,000,000</b>		<b>5,995,000,000</b>	<b>27,780,000,000</b>

To-day the annual growth of wood is approximately six billion cubic feet. The possible growth, provided the lands are properly restocked after cutting, and protected, is conservatively estimated at twenty-seven and three-quarters billion cubic feet per year. Not all of this annual growth would be available for manufacture into liquid fuel, as provision must be made for lumber and numerous other forest products.

Each year approximately twenty-six billion cubic feet of wood (far in excess of the present growth and taken principally from the accumulation of virgin timber) are removed from the forests, distributed as shown in the following table.

*Amount of Wood Removed Annually from the Forests of the United States.*

Cut	Equivalent in Standing Timber Cub Ft.
Lumber . . . . .	8,913,300,000
Fuelwood. . . . .	10,450,000,000
Other products. . . . .	4,955,000,000
Destroyed by fire, insects and fungi . . . . .	1,739,000,000
<b>Total . . . . .</b>	<b>26,048,915,000</b>

Out of this total cut, at least 4 800 000 000 cubic feet of the lumber are lost through waste in the woods and at the mills. Adding to this the 1 730 000 000 cubic feet destroyed by fire, insects, and fungi gives a total of 6 530 000 000 cubic feet of wood annually wasted which should be available for liquid fuel, without encroaching upon the supply needed for other purposes. Furthermore, the possible annual growth (27 750 000 000 cubic feet) exceeds the annual requirements (26 000 000 000 cubic feet) by 1 750 000 000 cubic feet, furnishing an additional 1 750 000 000 cubic feet, for liquid fuel. Finally, the increased growth which will follow intensive forest crop management, particularly the removal of small wood in thinnings, should amount to not less than 10 per cent of the possible growth, or 2 750 000 000 cubic feet. This gives a total of 11 000 000 000 cubic feet, as summarized below.

*Estimate of Amount of Wood for Liquid Fuel which could be secured from Forests of the United States without Encroachment upon Supply of other Forest Products.*

	Cubic feet
Waste in the wood and at the mills . . .	4,800,000,000
Losses from fire, insects & fungi . . . (taken out in thinnings)	1,730,000,000
Excess of possible growth over annual cut (taken out in thinnings)	1,750,000,000
Increased growth due to more intensive crop management . . . (taken out in thinnings)	2,750,000,000
<i>Total . . .</i>	<b>11,030,000,000</b>

In making a calculation of how much liquid fuel this 11 billion cubic feet of wood will produce, a cubic foot of wood is taken as weighing 30 lb and a ton of wood as yielding 15 gallons of alcohol. On this basis the 11 000 000 000 cubic feet of wood will furnish an annual output of 2 475 000 000 gallons of alcohol or 33 per cent. the total amount of alcohol needed to replace the present output of gasoline.

The cost of the raw wood laid down at the manufacturing plant is estimated to average 25 cents per gallon of alcohol produced by present methods, although where the proper region and species are chosen this figure may be reduced to 7 cents a gallon. It remains for the chemists to develop improved methods for utilizing the cellulose more completely, thereby increasing the output of liquid fuel secured from a ton of wood.

Professional foresters may be expected to co-operate fully with the chemists in their efforts to utilize wood as liquid fuel for at least two reasons: firstly, because utilization of waste in the woods and at the mills clears the forest of material now unsaleable which is often a dangerous fire and insect risk, and secondly, because the opportunity to dispose of small trees in thinnings will make more intensive forestry possible, and this in turn will increase the quality and quantity of forest crop production.

It is realized that the utilisation of wood as liquid fuel on a large scale is not likely to come for a decade or more. In order to have available when needed the largest possible annual supplies of wood, forested areas must without delay be protected, scientifically cut, and completely restocked. For this reason the Author asks for the support of the American Chemical Society in providing for the more satisfactory control of the nation's forest resources.

### LIVE STOCK AND BREEDING.

#### HYGIENE

61 - International Conference for Defence against Epizootic Disease, Paris, May-June 1921. — MASSE, A., in *Comptes rendus des séances de l'Académie d'Agriculture de France* (Meeting of June 1, 1921), Vol. VII, No. 21, pp. 481-487. Paris, June 1921.

At this International Conference all the States of Europe were represented as well as a large number of the States of North and South America, Asia and Australia.

The conclusions arrived at may be summarised under 3 heads:

1) As regards rinderpest, it was decided that as soon as this disease makes its appearance in the territory of any State, it is the duty of the neighbouring States to close their frontiers not only to cattle, but at the same time to other species of animals which not being susceptible to the disease, are not generally regarded as likely to spread it.

Owing to differences of opinion regarding the pig as a carrier of disease germs, the Conference was of opinion, that the scientists of the different countries should be requested to direct their investigations to the danger of infection caused by the transport of certain animals, and even of some animal products, including frozen meat. The Delegate of Poland drew the attention of the Conference to the fact that to require the destruction of all animals suffering from rinderpest (a disease very generally prevalent to a greater or less degree) would entail the complete destruction of stock, and the Conference in the light of this objection limited itself to passing a resolution recommending the various Governments to enforce the destruction of animals attacked by rinderpest.

It was next laid down that the first duty of infected countries towards their neighbours was to warn the latter immediately of the presence of serious diseases and to keep the neighbouring states informed of the minutest details connected with the course of the malady.

2) The second question dealt with the measures that should be taken by the States to guarantee that all stock imported into other countries is perfectly healthy and free from any suspicion of infection. The Conference decided, that a period of quarantine before shipping would best serve the purpose. It also considered it highly desirable that the States should agree upon an identical form of certificate, giving guarantees of equal value from whatever country the stock was imported.

3) Thirdly the conference decided to establish a permanent bureau at Paris for the purpose of studying the measures to be adopted against epizootic disease, and of publishing an international Bulletin containing

precise information respecting the sanitary condition of each country as regards rinderpest, foot-and-mouth disease, contagious peripneumonia, anthrax, sheep-scab, rabies, glanders, dourine and swine-fever, as well as reports of the researches carried on in the different laboratories.

- 62 - **Mexican Whorled Milkweed (*Asclepias Mexicana*), a Plant Poisonous to Live Stock in the United States.** — MARSH, C.D., and CLAWSON, A. B., in *U. S. Department of Agriculture, Bulletin* 969, 16 p., Tables 7, Plates 2. Washington, October 1921.

*Asclepias mexicana*, which grows in California and Nevada, has long been considered a stock-poisoning plant particularly dangerous to sheep, but nothing was definitely known as to the symptoms produced by it, or its toxic dosage.

The experiments made on sheep by the Authors have shown, that it produces effects similar to those caused by the other Whorled Milkweeds viz., *A. galioides* (1), *A. pumila* and *A. verticillata* var. *Geyeri*.

*A. mexicana* is about equal in toxicity to *A. pumila* and about  $\frac{1}{4}$  as toxic as *A. galioides*. The lethal dose is 6 times that of *A. galioides*, but about  $\frac{1}{2}$  that of *A. pumila*.

- 63 - **Contribution to the Study of the Tuberculosis of Domestic Animals in Reference to Human Tuberculosis** (2). — GRILLI, V. (Veterinario, Campobasso), in *La Clinica veterinaria*, Vol. XLIV, No. 18, pp. 518-523. Milan, September 30, 1921.

The author bases his remarks upon his personal observations which cause him to consider that cattle, swine and poultry can become infected with tuberculosis by the ingestion of food containing the bacilli of human tuberculosis.

These facts taken in conjunction with data collected by numerous practitioners and experimentalists, amongst whom is Dr. Carlo SARTI of the Institute of Hygiene of the Royal University of Modena (who succeeded in communicating both the human and bovine form of the disease to a dog by mouth, peritoneal and blood infection), would seem to prove that KOCH's bacillus, whether taken from man or cattle, is capable of infecting other animals. This micro-organism which is resistant to acids, immobile and essentially parasitic, is the commonest bacillus found among living beings and the one which owing to its latency makes the most victims throughout the animal world, for it spares no class and attacks equally mammals, birds, reptiles, amphibians and fish.

It thus follows that the morphological, cultural and other differences observed in the bacillus according to the species of its host, only denote the transitory forms that the micro-organism is able to assume. According to BEHRING, the bacillus would seem to adapt itself to the medium in which it lives, thus acquiring a greater or less degree of virulence according to the organism from which it is derived and the organism it infects.

Even in very different races of men or cattle, the bacillus can acquire

(1) See *R.* Jan. 1921, No. 68. (Ed.)

(2) See *R.* Oct. 1921, No. 973. (Nd.)

uch powers of infection, that it can be used in preparing vaccines such as FRIEDMANN's for prophylaxis against human tuberculosis, or KLIMMER'S (MIESSNER'S), which is recommended by the Dresden Institute of Veterinary Hygiene as a prophylactic against bovine tuberculosis and is prepared from tuberculous material obtained from cold-blooded animals.

- 64 - **Detailed List of Horse Strongyles in the Punjab, India.** — BOULENGER, C. L. (Pathological Laboratory, Punjab Veterinary College, Lahore), in *Parasitology*, Vol. XIII, No. 4, pp. 315-326, figs. 5, bibliography of 30 works. London, November 1921.

The author gives the anatomical characters and geographical distribution of the following intestinal worms: *Strongylus equinus* — *S. edentatus* — *S. vulgaris* — *Oesophagodontus robustus* — *Triodontophorus minor* — *T. intermedius* — *T. brevicauda* — *Poteriostomum imparidentatum* — *Cylicostomum coronatum* — *C. labiatum* — *C. porulatum* — *C. longibursatum* — *C. minutum* — *C. calicatum* — *C. goldi* — *C. catinatum* — *C. pseudocatinatum* — *C. pateratum* — *C. nassatum* — *C. insigne*.

- 65 - **Resistance of Various Breeds of Donkey to Skin Disease. Observations made in Tunis.** — See No. 81 of this Review.

- 66 - **The Piroplasmosis of Indo-China.** — SCHEIN, M. H., in *Bulletin Agricole de l'Institut Scientifique de Saigon*, Year III, No. 9, pp. 269-282, 1 plate. Saigon, September 1921.

The author first gives a general description of the symptoms, evolution and etiology of these affections, and then studies the various parasitic forms met with in Indochina, mentioning the different characters distinguishing them.

I. — **BOVINE PIROPLASMOSIS.** — A) *Piroplasmoses of the bigeminum type.* — It has not yet been possible to determine the species to which the Indo-China type belongs, but it is most probable that it should be relegated to *Piroplasma bigeminum* properly so-called, and not to either *P. divergens*, or *P. argentinum*. The author has not found such severe cases of infection in Indo-China as in other countries, where he has seen 1 out of 3 red blood corpuscles attacked. In Indo-China, even in the most serious cases only 1 in 50 of these corpuscles is infested by the parasite.

In this type of bovine *bigeminum*, the nuclear apparatus appears relatively large as compared to the mass of the haematozoon. The red corpuscles even when invaded by the parasite, show no apparent signs of alteration.

The presence of this form of *bigeminum* was observed by the author first at Nhattrang, in the calves used to supply the virus for the repeated transmission of rinderpest; other forms belonging to the type Gonderia occurred at the same time. The development of rinderpest revealed the two latent infections; it was extremely difficult to say whether the two types discovered represented two distinct species, or merely two forms in the life-cycle of a single species, all the more so seeing that many of the parasites appeared in intermediate forms which might be transition forms.

Although much smaller forms than *G. mutans* were found in all the animals, the presence of the *bigeminum* type was only discovered in about  $\frac{1}{3}$  of the calves.

Of recent years, *P. bigeminum* has only appeared at Nhatrang very exceptionally, in less than 0.5 % of the cases, whereas the small form is as common as in the past.

It seems therefore, that it is necessary to acknowledge the existence in Indo-China of the two different species.

The disease caused by the *bigeminum* type corresponds entirely with the general description given. This haematozoon can kill the adult animals in which it has developed, unless they have been rendered resistant in their youth by an attack of the same parasite.

B) *Gonderia* (or *Theileria*) *mutans* Type. — It may be said, from the information received, that nearly all the animals of the Nhatrang district are carriers of this parasite. On the other hand, no one has yet reported its presence elsewhere in Indo-China though it must certainly exist there, especially in places in the neighbourhood of forests.

Four forms of this parasite have been described. In the great majority of cases, only one parasite is found in each infected corpuscle, not infrequently 2 are met with, and certain animal carriers have more corpuscles containing 2 haematozoa than others. The author has sometimes found a larger proportion of corpuscles than in the case of the *bigeminum* type: one parasitised for 8 healthy. The infected corpuscles do not appear to be altered in any way.

The parasite does not seem to be pathogenetic and it occurs, although in small numbers, in animals giving every sign of perfect health.

Since, however, the development of diseases of different kinds (rinderpest, barbone), inanition, repeated haemorrhages all cause a rapid and sometimes considerable increase in the number of the haematozoa (which shows that the organism is certainly obliged to fight against them), an equilibrium is only attained when the host is able to make full use of all the means at its disposal.

*G. mutans* may therefore have something to do with the complications that arise.

Certain authors affirm that this form never causes haemoglobinuria; SCHEIN however has observed this affection in many individuals, but always in cases where the haematozoon had been aroused by the outbreak of rinderpest.

He has several times seen (always associated with *G. mutans*), parasites belonging to the remarkable group of *anaplasms*. The infection is light, only 2 to 5 of the parasites being found per 1000 corpuscles. The presence of this form has never been known to occasion any special disturbance.

II. — BUFFALO PIROPLASMOSIS. — A) *Bigeminum* type. — A parasite of this kind was discovered in a buffalo that had been used in rinderpest experiments and been cured of that disease. Very few of the haematozoa were found in the blood when it was examined. The blood had been injected without any result into another buffalo, a calf and a kid, in which *P. bigeminum* had not been discovered. According to the Author, however negative results do not prove anything, but as this form

differs morphologically from *P. bigeminum* it is most probable that we have here to do with a distinct species. The author proposes to call this parasite *Piroplasma bubali*, until more precise data are obtained.

B) *Theileria mutans* type (?) = *Nuttalia bubali* (?). — In 1908, the author reported, in the *Annales de l'Institut Pasteur*, a bacilliform piroplasm as being present in the buffaloes of Indochina, and since that date, this parasite has frequently been found in the young buffaloes of that country. The most common form of this haematozoon is ovoid. The bacillus form is shorter and thicker than the parasite found in ordinary cattle, and the nuclear mass does not show the characteristic transverse division into two portions. This leads the author to believe, that it is a distinct species, especially since the different endoglobular parasites appear to be strictly specialised as regards their host. Further, after the blood has coagulated, the bubalin serum is much lighter and less coloured than cattle serum, greatly resembling that of the horse. Thus the blood medium seems to be very different in the case of the two hosts.

The probable systematic position to be assigned to the small piroplasmic forms of the buffalo is considered in the study of horse nuttaliasis, for they seem nearly related to the parasite producing this disease.

III. — OVINE PIROPLASMOSIS. — The small number of forms that have been studied prevents the parasite of this disease being classified with any certainty, but it is not a piroplasm properly so-called and its pathogenetic power has not yet been determined. Indeed some of the forms examined give the impression of being nearly related to *Nicolliia quadrigemina* from their resemblance to the figures given by Prof. NUTTAL. No conclusion can however be arrived at owing to lack of data.

IV. — HORSE PIROPLASMOSIS. — *Nuttalia equi*. — In 1910, the Author reported the existence in Nhatrang of a horse piroplasmosis due, according to Prof. NUTTAL'S determination, to *Nuttalia equi*. This parasite had never been found in such large numbers. It occurred in nearly every form, oval, annular, tear-shaped etc., but never in true bacillus shape, although some fusiform or shuttle-like forms presented a certain resemblance to bacilliform parasites, but, contrary to what occurred in the case of *Gonderia* (*Theileria*) *mutans*, they are not functionally differentiated micro-organisms (gametocytes). The nuclear mass is never clearly separated into the two consecutive masses that had been pointed out by M. SERGENT, and noticed by the author in the bovine bacillary form in Indo-China.

For the same reason, the small form found in the buffalo, which never assumes this aspect, appears to be nearer akin to the *Nuttalia* of the horse, than to the bovine species of *Gonderia* (*Theileria*). If this view is correct, and the classification adopted by M. SERGENT is adopted, this parasite should be called *Nuttalia bubali*.

V. — DOG PIROPLASMOSIS. — The parasite inducing this disease, like the buffalo piroplasm, and for the same reasons, would appear to belong to the genus *Nuttalia*.

Although ticks are certainly responsible for the great majority of the forms of piroplasmosis, the Author has not been able definitely to prove

their complicity. As however the buffalo of Indo-China does not readily allow itself to be examined by a European, the presence of ticks may easily have escaped notice. Further the study of the ticks of Indo-China has scarcely been begun.

67 - **Diseases of Live Stock in Fiji.** — See No. 82 of this *Review*.

68 - **Piroplasmosis due to *Theileria parva* in North Africa.** — PRICOLA, A. (Direzione Veterinaria di Tripolitania), in *La Clinica Veterinaria*, Vol. XLIV, No. 18, pp. 503-512. Milan, September 30, 1921.

The blood of animals infected by a disease prevalent in certain parts of North Africa is found to contain *Theileria parva*, and at the same time KOCH'S corpuscles, which are supposed to be characteristic of the South African Coast-fever, are present in the spleen and lymphatic glands. The occurrence of these corpuscles has already been recorded by the author as a guide to diagnosis.

CARPANO described at the same time the life cycle of the parasite in the spleen and lymphatic glands. The description of the clinical form (with lesions of the abomasum) given by VELU in connection with the disease which exists in Morocco, agrees with that of CARPANO and the author. These observations do not prove the presence of Coast-fever in Libya, and no fact hitherto reported in any way demonstrated its existence in the country. The three epizootic diseases observed by the author in Tripoli and the disease which CARPANO describes at Bengasi, may be regarded as having been imported from the neighbouring French Colonies of North Africa. They might be termed "epizootic diseases of cattle grazing-grounds", to signify that they are not necessarily connected with the localities where they develop, but are imported with the cattle.

Coast-fever under the climatic conditions of the Maritime region of Libya has so far been a summer disease only.

It is unlikely that *Hyalomma aegyptium* is the agent of the transmission of coast fever which is probably due to some species of *Rhipicephalus* and amongst others to *R. sanguineus*.

The name "Mediterranean Coast-fever" cannot at present be justified. Until the contrary has been proved, it may be assumed that this disease does not exist in Sicily, Sardinia or South Italy. It has been stated, that the cattle of Southern Italy are immune to this fever, but the author reports that those of Sardinia and Sicily, as well as the animals of the podolic breed commonly kept in South Italy have been known to contract the disease. No cure exists but the author obtained excellent results with the following prophylactic methods:

a) The slaughter of all sick and infected animals. The flesh of cattle killed at the beginning of the disease has all the characters of sound meat. As was to be expected, it was used for human consumption without the slightest ill effects.

b) Destruction of the ixodes; 1) on the bodies of living animals by the use of the following mixture: 250 gm. of green soap dissolved by the action of heat in 2 litres of water to which are added by degrees, stirring

carefully all the time, 8 litres of crude paraffin (the short duration of the outbreaks renders it unnecessary to make tanks, or use arsenical baths ; 2) on the ground, by burning ; red hot sheets of zinc covered with hot embers are passed slowly over the ground.

As these cattle are butchers' beasts, losses can be reduced to a minimum as the meat is always fit for use.

- 69 - **Note on the Trypanosomiasis of the Dromedary (Debab)** (1). — SERGENT, P. and DONATIEN, A., in *Archives des Instituts Pasteur de l'Afrique du Nord*, Vol. I, Part 2, pp. 179-184. Tunis, July 1921.

As a result of their researches on the course of dromedary trypanosomiasis, the authors state that it much resembles human malaria, the best known of haematozootic diseases.

The acute stage in which death may supervene during a prolonged access of fever, is followed by a chronic stage ending in recovery or cachexy. This chronic stage is marked by sudden relapses, only lasting from 1 to 2 or 3 days, with intervening periods of calm during which the disease is latent, there is no fever and the peripheral blood is free from parasites. These conditions may continue from a fortnight to several months. These long latent periods preserve the virus of one season in a condition suitable for conveyance the following year by insect carriers. Hence the difficulty of adopting any prophylactic measures against these diseases, in which the vertebrate is the reservoir of the virus.

- 70 - **Critical Study of Some of the Nematodes of Camels in India.** — BOULENGER, C. L. (Pathological Laboratory, Punjab Veterinary College, Lahore), in *Parasitology*, Vol. XIII, No. 4, pp. 311-314, figs. 3, bibliography of 6 works. London, November 1921.

The author gives the anatomical characters and geographical distribution of the following species of nematodes found in the Indian camel: *Haemonchus longistipes* and *Nematodirus mauritanicus* Maupas and Seurat 1912.

- 71 - **The Animal Parasites of Foxes with special Reference to some Species of Hookworms (*Uncinaria*)** (2). — I. RILEY, W. A. (Chief of the Division of Entomology and Economic Zoology, Department of Agriculture, University of Minnesota, Minneapolis), An Annotated List of the Animal Parasites of Foxes, in *Parasitology*, Vol. XIII, No. 1, pp. 86-96, Bibliography of 34 works. London, March 1921. — II. RILEY, W. A. and FITCH, C. P. (University of Minnesota, St. Paul), The Animal Parasites of Foxes with special reference to Hookworms, in *Journal of the American Veterinary Medical Association*, Vol. LIX, New Series, Vol. 12, No. 3, pp. 294-305, bibliography of 8 works. Washington, June 1921.

The industry of breeding foxes, especially silver foxes, for the sake of their fur (3) has increased enormously of late years, but the breeder has paid but little attention to the few parasitic diseases attacking these

(1) See: R. Dec. 1918, No. 1368; R. Nov.-Dec. 1920, No. 1139; R. Nov. 1921, No. 1133. (Ed.)

(2) See R. July 1921, No. 736. (Ed.)

(3) See R. August 1921, No. 846. (Ed.)

animals, which in their natural condition appear to suffer little in this respect.

Now however when any factor affecting the health of the foxes or the condition of their coats, is of great economic interest, a careful study of the parasites infesting these animals is of considerable importance.

With the object of contributing to the knowledge of the parasitic affections of the fox, the author gives a detailed list, together with notes on the synonymy, anatomical characters, life-history and pathogenetic importance of the following animal parasites belonging to 9 orders, and to the following respective number of species: Protozoa 4 — Cestodes 16 — Trematodes 10 — Nematodes 20 — Linguatules 1 — Mites 3 — Ixodes 12 — Mallophaga 2 — Siphonaptera 6.

II. — The examination of certain specimens of faeces from three fox-farms showed that the severe losses among these animals, when kept under insanitary conditions, were chiefly due to parasites belonging to the genus *Uncinaria*.

A considerable number of hook worms have been reported for the fox. The authors mention the 3 most important species: *Ancylostoma caninum*, *Uncinaria criniformis* and *Uncinaria polaris*. and give a detailed description of their anatomical characters and life-history.

SYMPTOMATOLOGY. — The common symptoms of hookworm infestation are emaciation, poor coat and general cachexia. These conditions are however produced by causes other than hookworms, and the only sure method of making a positive diagnosis is an examination of the faeces.

PROPHYLAXIS. — It is most important that animals found infested with hookworms, ascarids or coccidia should not be accepted by the breeder before being subjected to thorough medical treatment at the seller's risk. Where this is not feasible, the animals should be isolated for a few days after purchase, carefully examined and treated if necessary.

In the construction of yards, great attention ought to be paid to drainage to avoid the passing of infection from pen to pen. For various reasons it is preferable to have the pens separated by a distance of 1 ½ ft. to 2 ft., to allow for drainage.

Advice is given as to the hygienic measures to be adopted for the floors of the pens, so that the soil may be easily disinfected. For this purpose the authors suggest spraying with burning oil.

TREATMENT. — The authors give the treatments recommended by HANSEN, HALL, DARLING and SMILLIE (1). The most practical method would seem to be the following: a capsule of oil of chenopodium, containing 1 to 3 minims according to the strength of the animal, is given about one or two hours after a small meal hidden in a piece of meat; 4 hours after the dose of oil, a large ration of liver, which acts excellently as a cathartic, should be fed to the patient, and the treatment repeated after 10 days.

(1) See R. December 1921, No. 1234. (Ed.)

- 72 - **Cystoid Forms of *Taenia serialis* in the Psoatic and Dorsal Muscles of Wild Rabbits and Hares in Sardinia.** — GALBUSERA, S., in *Giornale di Medicina veterinaria*, Vol. LXX, No. 41, pp. 657-660. Turin, October 29, 1921.

The author gives a brief summary of the discussions respecting the life-cycle and parasitism of *Taenia serialis* which differs from *Taenia coenurus* (*Coenurus cerebralis*), in the fact that its cystoid form is of somewhat rare occurrence, whereas this stage of *T. coenurus* is well known to all veterinary surgeons and meat-inspectors. The author states that the cystoid form of *T. serialis* is frequently found in the wild rabbits and hares of Sardinia. COBBOLD and CAGNY have also met with it in the squirrel, and STILES has found it in the horse, in the United States.

Although all other observers say that the usual habitat of this cystoid form are the large serous cavities and the subcutaneous connective tissue, the author has seen it only in the interior of masses of muscle, especially in the psoatic and dorsal muscles.

#### ANATOMY AND PHYSIOLOGY

- 73 - **Researches on the Rate of Growth of the Dairy Cow. Extra-Uterine Increase in Weight.** — BRODY, S. and RAGSDALE, A. C. (Department of Dairy Husbandry, University of Missouri Agricultural Experiment Station, Columbia), in *The Journal of General Physiology*, Vol. III, No. 5, pp. 623-633, Tables 5, bibliography of 14 works. Baltimore, May 1921.

The growth period of Jersey and Holstein cows is made up of at least 3 cycles; two extra-uterine cycles, with maxima at about 5 and 20 months after birth, and one intra-uterine cycle, the maximum of which has not yet been determined. The equation of an autocatalytic monomolecular reaction was found to give very good results when applied to the cycle having its maximum at about the 5th month. The values obtained from this equation in the case of the cycle reaching its maximum at about the 20th month were higher than the observed values, probably owing to the retarding effects of pregnancy and lactation.

- 74 - **Lactic Secretion in an Unmated Mule** (1). — GIROTTI, N. (Veterinario, Padua), in *La Clinica Veterinaria*, Vol. XLIV, No. 18, pp. 523-526. Milan, September 30, 1921.

The author describes a case (noticed by himself and verified by one of his colleagues), of a strong, healthy unmated mule 9 years of age, yielding a daily average of 3 to 4 litres of milk of normal quality from April-October 1920. The lactic secretion was again produced, without any stimulation and with symptoms of "heat," as soon as green feeding was resumed in the spring of 1921. It was however less abundant, being 1 litre a day if the animal was milked daily, and much less if some days were allowed to elapse without milking. The mule was always in excellent health.

As the lactic secretion continued all the time of the regular periods of "heat" it may be supposed that it was at all events largely due to a hormone produced by the ovule and ovary.

(1) See *R. Jan.* 1920, No. 98. (*Ed.*)

75 - **Experiments made in Egypt on the Digestibility of Bersim (*Trifolium alexandrinum*)** (1). — PRESCOTT, J. A., in *Bulletin No. 5, Sultanic Agricultural Society, Technical Section*, pp. 1-10, Tables II. Cairo, April 1920.

FEEDS AND  
FEEDING

Report of experiments covering a period of 5 days conducted in 1916-17 with sheep (of Leicester origin and local breeds), fed four times daily with fresh bersim. Determinations of the digestibility of two varieties of bersim were made ("Fahl" and "Misqawi"). The results obtained are shown in the following Table.

*Digestibility of each Constituent digested, vars. Fahl and Misqawi.*

	Total organic matter	Total nitrogenous matter	Albumi- noids	Ether extract	Woody fibre	Carbo- hydrates
<i>Fahl</i>						
January 2 . . . . .	68.1 %	74.8 %	73.1 %	59.0 %	45.6 %	76.9 %
February 2. . . . .	63.7	67.6	61.9	55.2	47.0	71.3
<i>Misqawi</i>						
Average of 7 determi- nation from 1 cut- tings. . . . .	69.1	73.0	69.2	49.9	60.5	74.0

The digestibility of these two varieties is therefore approximately the same, except that the fibre of Fahl appears to be less digestible than that of "Misqawi."

In estimating the feeding value of green bersim, the water content in the different cuttings should be considered.

The dry matter in "Misqawi" from January to March is about 15 %. The digestible constituents per ton of green bersim containing 15 % dry matter are as follows:—

Organic matter 91.0 kg.; — albuminoids, 15.5 kg.; amides, 3.2 kg.; fats, 2.9 kg.; fibre 20.1 kg.; carbohydrates 49.2 kg.

For the months of April and May, the feeding value per ton is considerably higher owing to the increase in dry matter. If however the water content has been determined, it is a simple matter to calculate the feeding value of any bersim.

An appended note gives data relative to the mineral matter content of bersim.

76 - **Brazil Beans, or "Mulatinos", a Variety of *Phaseolus vulgaris*, as a Stock Feed. Researches and Experiments Made in Germany.** — GOY (Communicated by the Königsberg Agricultural Station), in *Mitteilungen der Deutschen Landwirtschafts-Gesellschaft*, Year XXXII, Part 46, pp 661-662 Berlin, November 1921.

The nutritive value of Brazil Beans ("Mulatinos"), like that of other stock feeds recently introduced into Germany, has not yet been determined

(1) See R. May 1917, No 402 (*Ed.*)

by practical experience, although large quantities have found their way on to the market.

As in numerous cases the results of feeding these beans to stock had been reported to be unsatisfactory, the author thought it desirable to study more closely the food value of this variety of *Phaseolus vulgaris*.

The analysis of the beans (which are usually small, flat and of the colour of cocoa) gave the following results : Crude protein 21.26 % — Digestible protein 19.38 % — Fats 1.86 % — Crude fibre 3.23 % — Nitrogen free extracts 54.92 % — Ash 4.16 % — Water 10.89 % — Sand 0.12 % — Acidity 0.49 %. The protein and fat contents agree very closely with the corresponding averages determined for the horse-bean, and the nutritive value of the two may be regarded as equivalent.

At the Königsberg Agricultural Station, experiments have been made in feeding horses, cows and pigs with raw and cooked Brazil beans, with or without the water in which they were boiled. The following observations were made as to the effect on the different species of animals :

**HORSES.** — Horses utterly refused to touch the beans, and would not even eat them after fasting for several days.

**PIGS.** — Pigs were with difficulty persuaded to eat the beans raw, and took them unwillingly even when cooked.

An exclusive ration of 2 ½ kg. of beans fed to young adult pigs had no bad effect upon the health of the animals. The addition of a little salt, or other aromatic substances appears to render the beans more appetising, but they could never be used for fattening, as the pigs will not eat them readily.

**Cows.** — Cows ate the beans without any difficulty, whether fed crushed and raw or boiled. No diarrhoea or other bad effects were noticed. Since however there have been cases of severe diarrhoea among bulls and swine that have eaten large quantities of raw beans, it is better to give cows boiled beans, and perhaps to drain off the cooking water.

This new article of diet has not been found to affect milk production, the quality of the milk or the taste and quality of the meat.

77 - **The Concentrated Food "Fruges Lin", or "Nutritivo Squassi", in Feeding Cattle (1); Experiments Made in Italy.** — BRENTANA, D, in *Rivista di Agricoltura*, Year XXVI, No. 43, pp 618-621; No. 44, pp. 632-636, Parma, October 28, and November 4, 1921.

The concentrated food known on the market under the names "fruges lin," or "nutritivo Squassi" consists of a mixture, in constant proportions, of linseed-cake meal, molasses, tomato residue and uncrushed grape pips. According to the analysis made at the "Laboratorio di Chimica agraria della R. Scuola Superiore di Agricoltura" of Milan, its percentage composi-

(1) Successful experiments have been carried out with this food, as compared with bran, at the Agricultural Experiment Station of San Michele (Province of Trento). It was judged to be very suitable for draught and fat cattle.

See *R.* April 1921, No. 405. (*Id.*)

tion is as follows : Water 9.5 — Crude protein 15.0 — Crude fat 8.8 — Crude fibre 23.7 — Ash 5.8 — Nitrogen-free extract 37.2 — Digestible protein 10.62.

In the feeding experiments which lasted 30 days, the author used 19 cattle of the Brown Alpine breed ; he adopted the method of equivalent groups, and all his experiments were preceded by a period of observation to determine the effects of the ordinary ration, and by a period of transition.

The results are given in the following Tables, Groups B, F, H, serving as controls. The composition of the various groups was as follows : A, 2 young oxen 26-28 months old — B, *idem* — C, 1 young bull and 2 heifers of 12 to 13 ½ months. — D, *idem*, F, *idem*, F. G. H. each consisted of 2 young calves (one a bull and the other a heifer), from 3 to 4 months old.

TABLE I. — *Rations Fed (in kg.)*

Lots	Composition of ration			Ration Content in .				
	Hay	Outs	" Fruges lin "	Dry matter	Digestible protein	Digestible fat	Nitrogen- free extract digestible fibre kg.	Starch value kg.
A	9	—	1.5	9.36	0.58	0.20	4.40	3.53

(1) One calf fell ill during the experiment, through causes independent of the feeding.

During the preliminary observation period, the author found that with a ration of 2.5 kg. hay + 0.7 kg. oats per head and per day, the average daily increase in live-weight of the calves (both males and females), was 385 gm. per head. The 4 young oxen given 11 kg. of hay per head per day, increased 465 gm. in live-weight daily, and the young bulls and heifers fed 6 kg. per head, per day, gained on an average 540 gm. These data prove once again the advantages of giving concentrated foods to calves.

The "fruges lin" was slightly moistened and put into small wooden troughs. All the animals ate it quickly and with avidity especially the young oxen.

According to the Parma market prices, at the time of the experiment, viz., 53 lire per quintal for May hay, 120 lire for oats and 80 lire for "fruges lin," the nutritive unit of the three foods would cost respectively : 2 lire — 1.90 lire — 1.87 lire.

In other experiments, the "fruges lin" fed as a supplementary ration to cows during the lactation period and at the rate of 2 kg. per head and per day, was readily eaten, produced no disturbances of the system and had a favourable effect upon the milk yield.

78 - **Microscopic Examination of Flour from the Common Reed.** — GREVILLIUS, A. V. (Landw. Versuchstation Kempen), in *Die Landwirtschaftlichen Versuchs-Stationen*, Vol. XCII, Parts 5-6, pp. 195-208, figs. 23. Berlin, 1919.

Of recent years, the flour of the common reed (*Phragmites communis*), has been largely used in Germany as a cattle food ; it is obtained by drying and pounding the young plants cut before they flower. It is useful to be able to distinguish this meal and to assist in its identification ; the author gives a detailed description of the tissues composing the stem and leaves.

#### BREEDING CATTLE

79 - **A Mendelian Experiment in Crossing Aberdeen-Angus and West Highland Cattle: Experiments Made in Great Britain.** — WATSON, J. A., in *Journal of Genetics*, Vol. XI, No. 1, pp. 59-67, 1 plate separate from the text, bibliography of 14 works. Cambridge, April 1921.

These experiments were carried out with the object of determining in crosses between Aberdeen-Angus and West Highland cattle, the mode of inheritance of the horned and polled conditions and of colour differences.

The Aberdeen-Angus (polled) is black, with the exception that a small amount of white is permissible behind the umbilicus and on the end of the tail ; it has a smooth coat, short legs, and is stocky, wide, heavily-fleshed and small-boned.

Red calves are occasionally born. "Scurs," small, firm or loose, horny excrescences were once comparatively common, but have now been almost eliminated by selection. The West Highland cattle on the contrary have large spreading horns and a long and shaggy coat ; they are narrower in build and less heavily fleshed than the Aberdeen-Angus. They are also later in reaching maturity. Their colours are many, but only red and dun coloured animals were used in these experiments.

It was found in these crosses that the horned and polled conditions form a simple pair of Mendelian characters. The latter is completely dominant in the female, while in the heterozygous male, horn development is inhibited but not always suppressed.

These results are in accordance with those obtained by GOWAN (1) in first hybrids of crosses between the Aberdeen-Angus and various horned breeds. The distribution of horns in the  $F_2$  generation was as follows, in the present experiment.

	Polled	Hard "scurs"	Normal horns
Females. . . . .	15	—	3
Males (castrated) . . . . .	2	1	4
<i>Totals</i> . . . . .	17	1	7

Including the male with "scurs" as polled, we obtain the numbers 18 polled, 7 horned, which agrees very closely with the simple Mendelian ratio of 3 D : 1 R.

As regards colour, the experiments showed that black is dominant to red, and the colours behave as a simple Mendelian pair.

WILSON'S hypothesis (2) of multiple allelomorphs for colour is not in agreement with the results obtained, for whereas according to him, the various possible factor combinations (3) would be 2 blacks **B B** (homozygous or **B R** black (heterozygous) : 1 **B L** dun : 1 **R L** yellow, the obtained results were 2 black **B B**, or **B R** : 5 **B L** : 2 **R R**.

Dun is dominant to black, but the experiment has not shewn whether the dominance is due to a simple epistatic factor or a factor capable of modifying colours other than black.

81 - **The Stock-Breeding Institute of Sidi-Tabet, Tunisia.** — GINIEIS (Directeur de l'établissement d'élevage de Sidi-Tabet), in *Bulletin Mensuel de l'Office du Protectorat Français, Tunisie*, Year XIV, No. 122, pp. 81-93; No. 123, pp. 97-100; No. 124, pp. 113-116; No. 125, pp. 129-131. Paris, June-September 1921.

The author describes the organisation of this Institute, its objects, programme and work, as well as the progress it has already made.

The estate of Sidi-Tabet, which covers an area of 5 200 hectares is situated in the valley of the Medjerdah, 22 km. north-west of Tunis. Originally granted in 1866 to Count DE SANCY who established a Stud Station, the estate was made over to the "Société Franco-Africaine" in 1880.

In 1913, the Agricultural Authorities bought back the property with the object of founding a Stock-Breeding Experiment Centre.

I. ORGANISATION. — The land devoted to this Institute includes about 500 hectares in the plain and 146 hectares of mountainous or hilly country and is divided into two distinct areas situated on the banks of the Medjerdah, one at Sidi-Tabet and the other at Sidi-Ali. Although inconvenient in many ways, this division of the estate has some advantages. For instance, it allows the establishment of 2 autonomous farms. Sidi-Tabet will be the Experiment Station, the experimental farm devoted to the stud stock, breeds, élite individuals. Sidi-Ali will be the "economic" farm, the two farms being complementary from the financial, and technical standpoints.

II. OBJECT OF THE INSTITUTE: ITS PROGRAMME AND THE MEANS OF CARRYING IT OUT. — The first aim of the Institute is to study the theoretical and practical questions connected with stock-breeding in the colonies and to direct the systematic improvement of stock in Tunisia. Its work essentially consists in determining the best methods of keeping,

breeding, using and improving the native animals, solving certain difficult questions connected with stock-feeding in the colonies, finding the profitable equilibrium that should be maintained between stock-raising and crop production on an agricultural farm and finally supplying the colony and also foreign countries with élite animals for breeding purposes. These objects should be attained by carrying out the following programme : 1) strict selection of the native breeds ; 2) crossing the breeds of the country with carefully chosen imported breeds ; 3) maintenance of the purity of the breeding stock imported for improvement purposes. A comparison of the results obtained with each of the above methods should bring to light the most advantageous for general use in the country. In addition to the technical problem of the best means of obtaining good class stock, there is the still more important economic question which is solely concerned with the financial side of the operations. This forms the second part of the programme drawn up for the Station.

On the other hand, in order that they may be of general application, it is necessary in difficult experiments such as those connected with the improvement of stock, to take into account the average agricultural and stock-rearing conditions of a country. Hence and in order to carry out the economic programme, it was decided to have an agricultural farm annexed to the Station.

Finally it was recognised that no experiments could be complete or lead to the general improvement of stock, unless they were carried out on a large scale and with a number of animals of every species. In the remainder of the article, the author gives a complete account of the programme to be adopted in the case of the most important domestic animals (horses, mules and donkeys, and cattle), the work already carried out or in progress, the results already achieved and those still to be realised in the future.

III. HORSES. — The establishment of a Stud Station was the formal condition of the original concession made to Count DE SANCY by the Government of the Bey. He does not however seem to have made any attempt to improve the native horses, but to have wished to breed on the spot animals similar to those found in Paris. For this purpose DE SANCY imported pure-bred English, Anglo-Arab, Anglo-Norman, and even Scottish stallions and brood-mares. Most of the foals bred were however Anglo-Arabs.

During its management of the Station (August 1880 to October 1913), the Société Franco-Africaine aimed successively at two different objects. Throughout the first period (1881-1897), it tried like DE SANCY, to produce a fine saddle-horse suiting the taste of the time, but some more selective experiments were also made on the Arab and Barbary breeds. No prevailing idea seems to have directed these efforts beyond the wish to obtain some unusually fine specimens, and no attempt was made to improve the breed of the country.

During the second period, the Society adopted a more systematic method. The objects of its work were then threefold : 1) breeding pure-

blood Arabs : 2) breeding the Arab-Barbary horse ; 3) breeding mules from the rejected mares.

The production of pure-blood Arabs and of mules gradually increased in importance, but the number of Arab-Barbary horses reared diminished.

The Agricultural Authorities, when they took over the Station, kept the best of the pure-bred Arabs only and sold all the Arab-Barbary hybrids and the Barbary mares.

At the Sidi Tabet Stud Station they continued : 1) the selection of the Barbary breed ; 2) the breeding of good saddle-horses by selection of the Barbary and Arab horses ; 3) the breeding of draught horses by the selection of powerful Barbary horses and the repeated crossing of Barbary mares with Breton Stallions ; 4) the selection of the Tunisian pony.

1) As a result of numerous and varied crosses the Barbary breed tends more and more to disappear, and there is a risk of its being ousted by a heterogenous " population " with no fixed characters. Owing to its thriftiness and powers of resistance, the Tunisian-Barb is however superior to any of the other hybrids that have been obtained. This cross supplies excellent horses and brood-mares, many of the animals having size and bone.

Most of them are remarkable for depth of chest and powerful fore-quarters. In all cases however the hind-quarters are weak and badly-balanced, the croup being depressed, short, sharp and narrow and the hocks close and crooked. These defects can be remedied ; by liberal and regular feeding the dimensions of the breed can be expanded and the faults of the hind-quarters can be corrected by careful selection.

2) — a) The preservation of the native race is now more important than ever, seeing that the World War has proved the Barb to be one of the best of cavalry horses and an ideal mount for the trooper. By choosing and mating short, symmetrical, regular, short-legged individuals showing traces of good blood and breeding, an excellent saddle horse could doubtless be quickly obtained.

b) In addition to the Barb, pure Arab horses are also selected at Sidi-Tabet. Under the influence of the dominant idea originally governing horse-breeding at the Station, viz., the production of a fine mount, the main object in view was to obtain an elegant, tall horse of pure Arab blood with long lines. Remarkable specimens were bred which made the reputation of Sidi-Tabet throughout North Africa and supplied superb stallions to the Army Stud Stations. On taking over the Station the Authorities made every effort by selection and choice of sire to improve the former type, which is still preferred by many breeding experts, and at the same time to obtain a new type of average proportions, thickset, standing low, symmetrical and regular, recalling to a greater extent the classic Arab of the East.

c) In short, a comparison of the Barbary and selected Arab horse will show which animal is the better as a saddle horse, and will certainly direct the efforts of the Tunisian stock-breeders towards the production

of the Barb. by means of rigorous selection, or the breeding of the Arab through repeated crossing.

3) Although the mule and the ox must remain the chief draught animals for agricultural purposes and the extension of motor culture will decrease the number of animal tractors required, it is certain that a good draught horse would be most useful to the Colony. No such animal exists at present but the Station will show that it can be obtained.

The type of horse chosen for agricultural purposes is the post, artillery or omnibus horse weighing 500 to 550 kg., from 1.50 m. to 1.55 m. in height, short, short legged and well-balanced. Sidi-Tabet is trying to obtain it by two different methods: *a*) by the selection of heavy Barbary sires and dams weighing 500 kg. and over, large, massive and with heavy frames; *b*) by the repeated crossing of the above type of mare with the small Breton horse from Cornouailles, or the poor cantons of Léon, which is the only animal possessing sufficient thriftiness and endurance to withstand the wretched climate of Tunisia; *c*) the comparison between the draught Barb and the Breton horse suggested as its substitute will decide which is the better animal. It will then be possible for Tunisian breeders to adopt the method that has given the best results with the least expense.

4) In addition to the Arab another local breed, the Cap Bon and Mogod pony, will be kept at the Station. The qualities of this animal are not to be despised in spite of its small size. The type will be improved by selection.

RESULTS OBTAINED. — By a careful choice of the stallions obtained from the best Stud Stations of Tunis and Algeria, Sidi-Tabet has been able to make progress in breeding pure-blood Arabs. The old type however while keeping its air of breeding, height and fine lines, has acquired the bone and flesh which was to some extent lacking, and has become more powerful, more regular and more symmetrical. It has also been possible to obtain some large mares with short legs and of average proportions which are remarkable for their balance, the regularity of their fine lines and have an expressive square head, broad at the level of the brow, a straight profile, and large full eyes.

Thus in all the new products, the blood has been improved, the knees and withers are lower and the lines of the head have fined down. The first results are therefore most encouraging.

By increasing care in the choice of the stallion, and by strict selection for the desired end, Sidi-Tabet will succeed in breeding a race of Arabs whose bright coat, fine lines, general shape and characters of head will increasingly reveal their Eastern origin.

The Station at the same time continued to rear the Barbary horse. Of the 5 Barbary mares from the districts of Ebba-Ksour and Thala, 3 are used for breeding large draught Barbs or Breton-Barbs. Their foals are still too leggy, flat and loosely built. The other two mares are light, slender, more symmetrical and represent a rather handsome type of cavalry-mount. Both these colts and fillies are not wanting in breeding and symmetry, but their general balance leaves something to be desired

The next purchase of Barbary brood-mares will be chosen for their symmetry and balance rather than for their height, and thus the value of these experiments will be increased.

Comparison of the pure-bred Arab with the pure-bred Barb has shown that the former is superior as regards symmetry, elegance of line, signs of breeding, suppleness and good paces. In addition to these advantages which were easy to foresee, and already well known, the experiment proved, at least at Sidi-Tabet, that the Eastern horse is thriftier and easier to keep than the native animal, although few persons are aware of the fact. Barbary mares and foals eat a third of a ration more (hay and grain) than Arab mares and foals of the same weight and age. The author is uncertain whether this is merely a coincidence or a natural predisposition, as seems likely from the difference of build. Further comparisons made with a larger number of subjects should settle the point.

In spite of the results obtained, the increased girth of the original Sidi-Tabet Arab type, the creation of a smaller, shorter, more symmetrical animal nearer the Eastern model and also the selection of the Barbary breed, there still remains much to be done.

IV. DONKEYS AND MULES. — The object of the Station in regard to these animals is to improve the native donkey, to determine the best jack-ass for mule-breeding and to acclimatise foreign breeds with a view to breeding stallion donkeys on the spot.

The native breed consists mostly of small animals, but it also produces a certain number of strong female donkeys and good sized jackasses and although not of much service for mule-breeding, is yet worth improvement. At Sidi-Tabet this will be done by selection combined with repeated crossing with the foreign breed that experience will show to be strongest and best suited for the purpose. Since its organisation, the Institute has possessed: *a*) Savoyard jack asses; *b*) Poitou jackasses; *c*) Pyrenean jackasses. During the time they spend at Sidi-Tabet, which is from June to the following February (1), these animals take part in all the agricultural work with the mules and oxen belonging to the farm. They have the same food, are exposed to the inclemency of the weather and subject to the same periods of over-work. The long spell of draught work proves their dexterity, resistance and good working qualities.

During the service season, a certain number of donkeys remain at the Stud Station to serve the mares of the Institute, as well as those owned by the colonists and natives. Many of the donkey stallions retained in 1921, during the time they were working, served two or three times; the number of mares covered being over 350. The qualities of these donkeys as sires is proved by this repeated use and by an examination of the mule foals of both sexes running with the mares in the douars of Sidi-Tabet.

The following conclusions are the results of several years' observation.

1) All the breeds of donkeys imported into the Colony suffer much

(1) During the service season, the donkey stallions are distributed among the Stud Stations of the Institute or kept by the Colonists. (Ed.)

from the stings of insects, summer sores or other skin affections, especially during the hot weather. Putting the animals to work is one of the best prophylactics and cures, for the donkeys thus escape the continuous irritation and the attacks of the flies.

Although resistance to skin diseases is more an individual than a racial character, the Pyrenean breeds appear to be the most immune. The thick coat of the Poitou asses although making them more disposed to eczema, protects them very effectually against flies. For this reason though the heavy coat of the Poitou female donkeys is removed the first year they spend at Sidi-Tabet, it is allowed to grow afterwards and never clipped even during the intense heat of the summer as it protects them from insect attack.

As regards good working qualities such as strength and hardiness, adaptability to climate and cost of keep, the Pyrenean and Savoyard breeds are incomparably superior to the Poitevin. This donkey is heavy, wanting in muscle, squat, soon tired and of clumsy gait and unable to do prolonged laborious work, and hence unfitted for ploughing or the long journeys required of transport animals. The Pyrenean and Savoyard donkeys on the other hand do all the work of the farm. Their greater strength is the only thing which distinguishes them from the native breed which is also very resistant. Work is beneficial rather than harmful to these imported donkeys, making them strong and docile; it is also the best preventive and curative treatment of dermatosis and excites the sexual instinct of the stallions which become more ready and energetic in service.

The Pyrenean donkey readily becomes acclimatised to Tunisia, living and working like the native ass or mule. The Poitou donkey becomes fairly easily acclimatised and does well if worked moderately, but cannot stand hard and continuous exertion.

The former is not only more resistant but also more profitable to the farmer, who finds in his Pyrenean donkey a powerful stallion as well as a worker paying for the greater part of his keep.

The two breeds differ in their capacity for reproduction in the same manner as in their aptitude for work. The Pyrenean jackass (like the Savoyard ass) is relatively ardent, whereas the temperament of the Poitou stallion is colder, the mare has to be kept with it and often there are long periods of waiting before copulation. The productive capacity is difficult to estimate, and depends upon the female as much as upon the male, being especially affected by the state of "heat" in the mare. At Sidi-Tabet, none of the breeds showed any characteristic difference in this respect.

The heaviest mortality has been found among the Poitou donkeys which are more liable to skin complaints and predisposed to chronic splitting of the hoop.

The Pyrenean jackass is indisputably superior to the Poitevin on account of its lower price, the fact that it can be used as a work animal as well as a stallion, its sexual ardour, lower disease and death rate, and

the favour in which it is held by the Arabs, and should certainly be recommended for mule-breeding and for the improvement of the native stock. Further experiments will show whether it can hold its own against the Syrian donkey, or even the improved native donkey.

MULE-BREEDING INDUSTRY. — Since the foundation of the Institute some of its Arab and Barb mares have been served by Pyrenean and by Poitou donkeys. These experiments taken in conjunction with the results of numerous observations made on the mules out of native mares served by Sidi-Tabet or native asses have led to important conclusions. Arab brood mares mated with Pyrenean and Poitou donkeys produce fine, strong, symmetrical, quick, docile, well-balanced mules with long free paces.

Mules out of Barb mares are slighter, show less marks of breeding, are sometimes slightly crooked in the hocks and have shorter paces. This first series of experiments thus proves that the substitution of the Arab for the Barb would not decrease but rather improve the mule-breeding qualities of the native race.

The facts regarding the best donkey stallion are even more definite. The jackass of the country sires nervous, narrow framed, small mules, which are so much inferior to the products of the same mares when mated with Pyrenean donkeys that an increasing number of natives take their brood-mares to Sidi-Tabet, in order to have them served by the donkeys belonging to the Institute.

The mules out of Poitou mares are short, squat, thick-set, short-legged and clumsy-looking on account of their large heads, and will perhaps prove susceptible to summer sores and the stings of flies. They are as yet too young to be put to work. Here again the Pyrenean male donkey shows his superiority. His offspring may be lighter and slighter than the progeny of the Poitou donkey stallion but they are taller, quick, wiry, agile, strong and resistant and when 4 to 5 years of age, they seem indefatigable. During the summer of 1921, they stood the trying work of hay-making, harvesting and ploughing quite as well as the native donkeys.

The Savoyard donkey has sired excellent mules showing great powers of resistance, even in S. Tunisia.

The proposed programme is far from being completed. Not only have the experiments hitherto made been too few and of too recent date to warrant any definite conclusions, but it will also be necessary to carry out numerous additional experiments with the breeds of mares and jackasses already at the disposal of the Institute, as well as to try mating Breton × Barb hybrids with Syrian donkey stallions.

V. CATTLE. — The author confines himself to the programme for the improvement of cattle, which is much more complex than that for the improvement of the horses and includes a number of difficult, intricate and interdependent questions chiefly connected with the factors of environment. Many experiments will have to be undertaken with the following objects: 1) the discovery of the best animal; 2) the study of the different principles to be observed in cattle rearing. Improvement

will have to be effected by selection combined with crossing. The native animal is worth selection as it is not without good qualities. Thickset and short legged, it is remarkable for the height and width of its chest, which is only a little above the ground, its broad ribs and powerful, solid, muscular fore-limbs. Unfortunately its hind-quarters are distinctly bad, the croup being short, sunken, narrow, the thigh thin, the haunch sharp and flat, the legs slender, and the hocks close and crooked.

With all these defects, the Tunisian ox is still a first class draught animal. Its small size hides an unusual degree of strength, it can resist privations and heavy work to an extraordinary extent, and its qualities as a producer of beef though not so good are not negligible. It fattens with surprising ease and rapidity, but it is late in coming to maturity, and its meat is tough and deficient in flavour. In spite of their finely shaped udders the Arab cows give but little milk. Most of them only yield 4-6 litres a day, though some supply as much as 8-10-12 litres. Their defects chiefly depend upon the wretched way in which they are managed. Under more satisfactory conditions, the animals could perhaps be improved and the milk yield increased to the point of making the keeping of Arab cows a profitable undertaking.

As always happens, selection will remain the favourite method, for it is the easiest to carry out, the most economical, and the surest in its results.

As regards crossing, the difficulties though by no means slight are less in the case of cattle than of horses. The chief point is to ascertain whether the work will pay, and to be sure that the care, trouble and outlay entailed will meet with an adequate return.

Of the various systems of crossing, continuous crossing will be tried under all the given conditions with the object of a permanent improvement in the appearance of the animals. Industrial crossing will merely be practised for commercial purposes, and only in very rare instances will recourse be had to alternative crossing and the rearing of half-breeds.

82 - **Live-Stock Industry in Fiji.** — RAINEY, W., Agricultural Circular issued by the Department of Agriculture, Fiji, Vol. I, No 7, pp. 119-132. Suva, 1920, in *Tropical Veterinary Bulletin*, Vol. IX, No. 3, pp. 183-188. London, August 1921.

LIVE STOCK

The approximate numbers of livestock in Fiji are :— Cattle, 80 000 — horses and mules, 10 000 — sheep, 1 000 — goats, 6 000 — and pigs, 4 000. The annual birth-rate of cattle is estimated at 10 000. On subtracting the animals killed for meat, exported, or dying from disease, we have a net increase of 2 000 head per annum.

CATTLE. — The supply of meat exceeds the demand, and consequently the price paid to the grower is low, but there is not sufficient excess at present to allow the development of an export trade.

In view of the cost of clearing, cultivating, fencing and weeding, it is not profitable for Europeans to develop land for cattle production, except as a side-line in coco-nut plantations. The supply of cattle is kept up

and increased by the Indian small-holder, who on an average has two cows and two working bullocks. The average weight of a 3 to 4 year-old bullock is from 300 lb. to 400 lb., and the average price per beast is £7.5. at Suva, or, £6.25 at Lauvoka. The average carrying capacity of the best flat land in the wet belt of Fiji is one animal to the acre. The only profitable form of cattle farming for the European grazier would be to purchase mature cows and store bullocks for fattening purposes. There are few self-supporting grazing-grounds and these are on river flats with Para grass (*Panicum molle*) for pasture. The scope for more graziers is therefore limited; it would be difficult to make a success of cattle-farming in the dry belt, on account of the small number of pastures available for fattening without handfeeding.

It is unlikely that the Islands can compete with temperate climates in the export of butter for the world's market. There is however good reason for assuming that the percentage of butterfat in the milk of the Fijian cow is actually higher than could be obtained in temperate countries from a similar class of cow under the same conditions of feeding.

Practically the only export trade is the shipment of a few bullocks each month to the butchers of Tonga and Samoa.

One enterprising commercial firm has built up an important trade in the victualling of ships with fresh meat and has in hand the experimental breeding of Indian cattle on a large scale.

A cross between the Zebu (Indian bull) and a European strain of cattle is most likely to prove the best breed for Fiji, except for high grade dairy farming, for which purpose a pure strain of Holstein will probably give the most satisfactory results.

The dry belt although it affords no hope of further development for cattle, still offers good prospects of development as a sheep country, but further investigation is needed to ascertain whether ewes are profitably fertile in Fiji.

**HORSES AND MULES.** — It is considered that these islands can supply themselves with both horses and mules, provided reasonable care is observed in the breeding and feeding of foals. Draft horses are chiefly in demand, and should be bred from the Suffolk Punch or Percheron strains. It may however be found on examination that it does not pay to breed horses in Fiji, when a great horse-breeding country like Australia is near and ready to supply any number of animals at moderate prices. On the other hand, it ought to pay well to breed mules (which could easily be done by mating good imported jack-asses with good country-bred mares), and these animals are considered the most suitable for the conditions of plantation work.

**LIVE-STOCK DISEASES.** — The author mentions the following diseases as being of common occurrence in Fiji: 1) *bovine tuberculosis*: the number of infected animals varies from 2 % in some parts of the dry belt to 20 % in some parts of the wet belt. — 2) *Ulcerating tumours of the eyes and back of cattle and legs of horses*. These tumours are due to the infection of sores caused by a larval nematode (apparently *Habro-*

*nema*) ; the disease is known as "Tona" in Samoa — 3) *filariasis* of dogs — 4) *Mange* — 5) *Scour* in calves — 6) *Osteoporosis* in horses.

PASTURAGE. — Remarkably little progress has been made in the cultivation of good grass. The only valuable pastures at present consist of Para grass growing on alluvial land. The grasses best suited to local conditions seem to be those of the *Panicum* family. With the exception of a small-leaved trefoil, Para grass, Guinea grass (*Panicum maximum*), and an upland variety of *Panicum*, there appear to be no grasses growing and propagating naturally in Fiji that are worth cultivating. Buffalo grass (*Buchloe dactyloides*) has been introduced experimentally and appears to do well, Rhodes grass (*Chloris Gayana*) is also being tried.

CONCLUSION. — In the author's opinion, the future of the cattle trade in Fiji depends upon several factors, of which the most important are the following : 1) the discovery of suitable grasses for upland pastures — 2) the control of weeds, especially of *Clidemia hirta* — 3) the establishment of a remunerative opening by means of a freezing or canning factory — 4) the creation or improvement of roads.

83 — **The Live-Stock of Italian Somaliland: Census of February 1, 1921.** — *Mimandro delle Colonie, Ufficio Affari Economici, Bollettino di Informazioni*, Vol. IX, Nos. 4-5, pp. 278-280. Rome, May-June, 1921.

The live-stock of Italian Somaliland is fairly numerous as is shown by the census of February 1, 1921, which was taken by counting the animals at the watering-places and gave the following figures :

*Live-Stock of Italian Somaliland.*

	Upper Uebi Scebelli Commis- ariat	Middle Uebi Scebelli Commis- ariat	Lower Uebi Scebelli Commis- ariat	Upper Juba Commis- ariat	Totals
Camels . . . . .	181,578	105,822	97,485	1 716,793	2,101,678

Horses, donkeys, and mules .	4,360	3,896	621	2,171	11,048

84 — **The Val di Chiana (Tuscany) Breed of Cattle and its Improvement** (1). — LAMBARDI, M., in *Giornale di Agricoltura della Domenica*, Year XXXI, No. 49, p. 389, figs. 2. Piacenza, December 4, 1921

The "chianina," or Val di Chiana breed, is the tallest of all the Italian breeds of cattle. Its home is in Central Italy (Tuscany and part of Umbria), but it has been introduced, for the purpose of improving the stock, into other parts of Italy including Umbria, Romagna and the Marches. This breed is of pure local origin, as was shown by Dr. Francesco MARCHI in "Atavismo nella razza bovina di Val di Chiana" and by Prof. Ezio MARCHI in "Razza bovina di Val di Chiana." It has been obtained by the progressive improvement of the local race brought about by the better conditions of environment and feeding and the introduction of proper housing which were the results of draining the valley in 1830. The occur-

rence of albino individuals, called "mucchi," is attributed by D<sup>r</sup>. F. MARCHE to an excessive amount of refinement; depigmentation is to be observed in all breeds of cattle that have been improved to the highest point, as is shewn by the Charolais race. As the number of "mucchi" had risen to the high figure of 25 %, the Val'di Chiana breeders decided to use for sires, less highly bred bulls that possessed all the characters of the race to a marked degree. It was found that none of the offspring of these animals proved to be "mucchi," which explains the fact that in hilly districts where the breed is hardier, the phenomenon of albinism is unknown. The "mucchi" are well-formed and good meat producers but have little capacity for work.

One of the objections made to the breed is that the animals are too long-limbed, a defect however which does not exist in the cows or bulls (that is to say the selected males), nor in the finest oxen.

The example set by buyers from other parts of Italy who choose the shorter-legged bulls for improving their stock has found imitators in the original home of the Chianina breed, so that the defect of excessive length of limb is disappearing to the great advantage of the beef and working qualities of the animals.

The author advises the breeders of the cattle to collaborate and draw up a Herd-Book.

85 - Comparison between the Milk Yield of Young Cows and Mature Cows. Researches Made in the United States. — HOOPER, J. J. (Department of Animal Husbandry, University of Kentucky, Lexington, Kentucky), in *Journal of Dairy Science*, Vol. IV, No. 5, pp. 451-452. Baltimore, September 1921.

With a view to determining the milk yield of a mature cow from its performance when young, the author studied all the results of the official milk yield competitions (for which 800 dairy cows had been entered) in the United States. The data collected are given in the following Table;

*Comparative Annual Milk Production of Young and of Mature Jersey Cows.*

Age of cows	No. of cows	Annual milk yield	Milk yield expressed as % of maximum production	Animal fat yield per cow	Fat yield expressed as % of maximum production
2 years. . . . .	278	3042 kg	74 %	153 kg	73 %
3 " . . . . .	126	3400	82	163	81
4 " . . . . .	112	3733	91	204	94
5 " . . . . .	91	3729	91	200	92
6 " . . . . .	60	3851	94	209	96
7 " . . . . .	47	4095	100	216	100
8 " . . . . .	29	3971	97	210	97
9 " . . . . .	25	3954	97	216	100
10 " . . . . .	11	4031	98	211	97

(1) See R. ZAPPA, *The Cattle Industry in Italy at the Present Day*, R. May 1914, pp. 772-783; R. June 1914, pp. 712-716. (Ed.)

This Table shows that a 2 year-old cow yielding 3042 kg. of milk, and 153 kg. of fat will give at the age of 7 years, when it has attained its maximum production and can be regarded as mature, 4085 kg. of milk and 216 kg. of fat. When it was only 4, however, its milk yield exceeded 90 % of the maximum production, so that after its third calving, a Jersey cow must be regarded as practically mature.

The maximum yield is maintained until the cow reaches the age of 10.

86 - **Methods Adopted for Improving Live-Stock in Tunis.** — See No. 81 of this *Review*.

87 - **Cattle Rearing in Fiji.** — See No. 82 of this *Review*.

88 - **Turkey Rearing in Sologne, France.** — DELAMARE DE MONCHAUX, in *La Vie aux champs*, Series III, No. 23, pp. 11-12. Paris, November 1921.

POULTRY

The enquiries made by the Central Agricultural Committee of Sologne, together with the Report presented to the World's Congress of Aviculture held at the Hague, and the figures furnished by the Chief of Commercial Services to the Orleans Railway Company show that shortly before 1914, 600 tons of turkeys were annually dispatched on an average from the principal Stations of Sologne, the maximum and minimum consignments being respectively 800 and 500 tons.

Taking the average weight of the birds (males and females), at 6 kg. per head, the number of turkeys annually sent to England, one year with another, is reckoned at 600 000, without counting 100 000 destined for other markets.

In order to supply the local demand and have sufficient turkeys for breeding purposes, the number of these birds kept before the War in Sologne was very large.

In 1918 and 1919, the export figures fell to 50 tons but rose again in 1920 to 150 tons.

There are many commons in Sologne, which are a great assistance to the turkey-breeding industry. Although the substratum of clay beneath the Orleans sands retains the rain-water, thereby causing damp and fogs which are unfavourable to poultry-rearing, the splendid results obtained before the War prove that the turkey-breeders have learnt how to triumph over these obstacles. They do not allow the birds to be out late, for the fogs that often arise at nightfall are very injurious to young turkeys. Careful hygiene and a strengthening diet help the chicks to get over the "crise rouge." Laboratory experiments are now being carried out for the purpose of discovering the cause of this disease which seems to be a perityphlo-hepatitis due to the presence of intestinal round worms belonging to the genus *Heterakis*. The author has himself frequently found this worm ("ver rouge") in turkeys attacked by the "crise du rouge". Diphtheria has also often caused the death of many turkeys.

In spite of the difficulties attending turkey-rearing, it may again become a flourishing industry in Sologne. Fat turkeys are bought by

the flock from the breeders by merchants who kill the birds and send them in crates to London. A certain number of turkey-hens are sent to Paris. They are smaller birds than the cocks, but more delicate. Before the War, the Sologne Committee tried to improve the conditions of sale, killing and dispatch by making a tariff with prices proportionate to the weight of the birds (the fine specimens being marked at a higher rate), and by substituting sale by weight for sale by flock. The Committee also advised the use of isothermic cars which would prevent any fear of the turkeys not arriving fresh in years when the weather was mild.

All these schemes were interrupted by the War. It would be advantageous both to breeders and merchants if they were now carried out.

Sologne turkeys in London find serious competitors in the Italian turkeys which are smaller, but earlier birds.

The French breeder would have to defend and protect his trade in this market.

89 - **Shortening the Incubation Period by Exposing Eggs to Radium Emanation; Experiments Made in Austria.** - WIENINGER, EG, in *Wiener Landwirtschaftliche Zeitung*, Year LXXI, Nos 92-93, pp 461-465. Vienna, November 19, 1921.

A communication made by the author to the World Congress of Aviculture held at the Hague in September 1921 (1). It gives the results of his five-years' researches undertaken to determine the effect exercised by a radium emanation upon incubation : 1) in an incubator with a constant supply of hot water ; 2) in an incubator heated with hot air ; 3) under a broody hen.

The hygroscopicity of the air in the incubators being from 55 % to 65 %, the temperature varied from 38.3° C to 40.6° C.

In order to expose the eggs to the emanation, the bromide of radium enclosed in ebony boxes 2 cm. in diameter and covered with a thin sheet of mica, was introduced into the apparatus, 20 cm. above the eggs.

The experiments proved that the duration of the emanation and the amount of radium employed had no bad effect upon the hatching out of the chicks.

Of the artificially incubated eggs 95.2 % hatched, which is remarkable considering that the experiments were carried out from November to January which is, as a rule, a bad season for the fertilisation of eggs. Further, the incubation period was shortened by 4 to 6 days.

The chickens from the eggs exposed to the emanation were unusually strong and grew very fast ; at the end of 6 weeks, they had attained twice the size of the control birds.

The pullets began to lay after the 5th month and continued producing eggs almost without interruption from August to February.

As there is no difficulty of technique to be overcome, and only a question of obtaining the necessary amount of bromide of radium (50 to 100

(1) For detailed information, see the author's work : *Der Einfluss der Radiumemanation auf die Abkürzung der Brutdauer*. Neutitschein, L. V. Enders. (Ed.)

mg.), the author is of opinion that the process he describes could well be carried out, in future, in practical chicken incubation.

- 90 — **The Comparative Efficacy of Animal and Plant Protein in Stimulating Egg Production: Duck Feeding Experiments in the Philippines.** — GOSCO ANDRES, in *The Philippine Agriculturist*, Vol. IX, Nos. 8-9, pp. 195-207. Tables 8, bibliography of 8 works. Los Baños, March-April 1921.

Experiments previously carried out by KEMPSTER (1), ROBINSON (2), AHRENS (3), and FRODA (4), had shown that animal protein has much more effect than plant protein upon the egg-production of fowls.

With the object of determining which of the two kinds of protein gave the better results in the case of ducks, the author made an experiment, lasting for a year, at the College of Agriculture, University of the Philippines.

The birds used in the experiment were divided into two groups, A and B, each containing 9 ducks and 2 drakes. They were fed in addition to their basal ration (a mash of equal parts by volume of unhulled bran), snails and copra meal respectively.

Details are given as to the method of carrying out the experiment and the treatment and feeding of the ducks.

The birds of both groups lost in weight during the period of the experiment. The loss was however more pronounced in the case of the copra-meal fed birds.

Each bird in the snail-fed group consumed 39.26 kg. of mash and 21.30 kg. of snails between July 20, 1918 and July 19, 1919, while each bird of the copra meal-fed lot consumed 33.10 kg. of mash and 12.30 kg. of copra meal during the same time.

The ducks in group A laid on an average 71.95 eggs per head per annum, while the average number laid by each duck in group B was 24.39. The average weight of an egg was 57.81 gm. in group A and 54.30 gm. in group B.

The eggs produced in group A had a fertility percentage of 88.19 % while that of the eggs produced in group B was 79.50 %.

On the other hand, the mortality among the ducklings of group A was greater than among those of group B.

- 91 — **Silkworm-Breeding in Tripolitania.** — *Ministero delle Colonie, Ufficio Affari Economici, Bollettino di Informazioni*, Vol. IX, Nos. 5-6, p. 277. Rome, May-June 1921.

SERICULTURE

The earliest attempts in silk-worm-breeding in Tripolitania date back to the year 1915. They were undertaken in the first place in order to discover whether the country was suitable for silk-worm breeding and were

(1) See R. Nov. 1917, No. 1047. (Ed.)

(2) ROBINSON, I. H., *Principles of Poultry Culture*. New York, 1912, p. 586. (Ed.)

(3) AHRENS, A. B., A Study of the Effects of Cotton Seed Meal versus Beef Scrap on the Egg-Production, Fertility and Vitality of Poultry, in *Oklahoma Agricultural Experiment Station, Bulletin No. 122*, pp. 1-20, 1917. (Ed.)

(4) FRODA, F. M., A Study of the Effects of Animal and Plant Protein in Rations for Laying Hens, in *The Philippine Agriculturist*, Vol. VII, pp. 235-253, Los Baños, 1919. (Ed.)

carried on until 1920 with the object of determining whether the industry was likely to prove profitable.

At the same time the local Government took steps to propagate among the natives the first principles of establishing a silk-worm-nursery and encouraged the cultivation of the mulberry-tree and the rearing of silkworms, thus laying the foundations of the sericultural industry.

The results obtained are as follows :

1) It is possible to have 2 rearings of silkworms a year in Tripolitania.

2) It is not necessary, as was once thought, to have special rooms built partly below the level of the ground.

3) The high temperatures due to the " ghibli " do not hinder the growth of the spring broods, for this wind has a favourable effect on the development of the silkworm and makes them more active.

4) Few of the natives in the Tripoli oases interest themselves in silkworm-breeding. The apathy of the great majority of the agriculturists has not yet been completely overcome by the large profits to be derived from the industry which needs great attention, although during a very short season only.

Sericulture in Tripoli has not yet attained the importance that is in store for it ; there are not many mulberry-trees in the country, and the few that exist are used by the agriculturists for other purposes. The Colonial Government continues to supply a large number of mulberry trees gratis, but it will be some years before the results of this assistance manifest themselves to their fullest extent.

92 - **Introduction of Sericulture into Colombia.** — *Revista nacional de Agricultura, Organo de la Sociedad de Agricultores de Colombia*, Vol. XV, No 205, pp. 3-6 Bogota, July 1921.

The " Escuela Superior de Agronomía y Medicina Veterinaria " of Medellín (Colombia), has begun the cultivation of mulberry trees, and has already planted about 900 with the idea of undertaking experiments in sericulture and of encouraging the spread of the industry in Colombia.

At Chinácota (Santander del Norte), a Jointstock company called " Compañía sericícola del Norte " has been started for the purpose of introducing and practising sericulture in the Municipality of Chinácota, in the Province of Ricaurte and in the Department of Santander del Norte.

In the Department of Santander the mulberry-tree is already grown, some of the landowners having several thousand trees. The few silkworm breeding experiments hitherto made show that sericulture is like to be very successful in Colombia.

93 - **The Possibilities of Rearing the Eri Silkworm *Attacus ricini* in Egypt** (1). — ADAIR, E. W., in *Bulletin de la Société entomologique d'Egypte*, 13th year, pp. 101-103. Cairo, 1921.

The author has succeeded in rearing Indian Eri silkworms (*Attacus ricini*), in Egypt, a country which he considers fairly suitable for silkworm-

(1) For the cultivation of *Attacus ricini* in Ceylon, see R. Feb. 1921, No. 189. (Ed

rearing, especially North Nubia from Assuan to Wady Halfa. In this region, which is very poor, large numbers of castor-oil plants are grown, and the wives and children of the natives employed in Cairo and elsewhere as servants would have plenty of time to tend the worms and wind the silk.

As however sericulture is more an economic than a biological question, the author lays stress upon the fact that, before urging the fellah to start silkworm rearing, he would require to be shown that his work would be remunerative, entail little expense, that the silk would find a ready market, and also that the time and labour necessary could not be turned to better account.

Experiments in silkworm breeding on a small scale have proved that the work can be carried on throughout the year in the region of the Delta, and during the winter months in Assuan. The author says however that if the industry is ever to become established in Egypt, it will be necessary to rear silkworms on a large scale in Nubia during the winter, and on a small scale in Cairo during the summer, in order to obtain eggs for the following winter, as the eggs of *Attacus ricini*, unlike those of *Bombyx mori* cannot be kept from one season to another.

ADAIR made many attempts before he succeeded in obtaining the silkworms. As the worms hatch out after 7 to 20 days according to the temperature, it was impossible to have the eggs sent from India, and the cocoons were forwarded in boxes large enough to allow the moths to emerge and mate on the journey. The changes of climate, especially during the crossing of the Red Sea, nearly always killed the chrysalids, or hastened the hatching of the worms, and it was not until 1917 that he received eggs laid en route and unhatched. Two Tables are given showing respectively: 1) the average number of days necessary for development at different stages and seasons (egg 10 to 20 days: larva 20 to 82 days: cocoon 19 to 48 days); 2) the average weight of 100 cocoons (from 39 to 50 gm.), and the number of cocoons per kg. (from 2000 to 4000).

## FARM ENGINEERING.

94 -- **The Power Farming Trial Week at Ondes, Haute Garonne, France.** -- BLANC, A. (Ingénieur du Génie rural, Chef de la Circonscription de Montpellier), in *Le Progrès agricole et viticole*, Year 38, No. 47, pp. 495-501, figs. 3. Paris, November 20, 1921.

AGRICULTURAL  
MACHINERY  
AND  
IMPLEMENTS

The Agricultural Office of the Sud-Ouest region held a trial week of power-farming from Oct. 12 to Oct. 17, at the Ondes College, near Toulouse.

The programme of this week included lectures, an exhibition of agricultural machines driven by electricity, and electric ploughing trials.

Two electric ploughing machines, both light windlasses with cables, were exhibited, viz., the DOUILHET windlass and the windlass of the Electric Motor Cultivation Society (S. F. M.).

The DOUILHET windlass is an extra-light machine. It weighs 750 kg.; its dimensions are about 1.30 m. × 1.20 m. × 2 m. The wheels are

provided with pneumatic tyres, and as therefore they have very little grip on the soil, the windlass has an anchor rod. The motor is of 12 H P and revolves under the tension of 220 volts. Two windlasses, one at each end of the field, send backwards and forwards a one-furrow two-way plough that can work to a depth of 20, 25 and even 30 centimeters. The possible traction of the cable is 300 to 400 kg.

The advance of the windlass after each furrow is effected by winding a steel cable on a drum fitted on the frame. One end of the cable is fixed to the drum and the other is fastened to a stake driven into the ground on the edge of the field. The drum is worked by hand by means of a winch, and the tractor travels on its cable.

In the absence of the makers, the windlass could not be tested.

The author is of opinion that the weight and power of the DOUILHET windlass are the lowest possible that can be used.

The machine is worked by 3 men, one at each windlass, and the third at the plough. Three men ploughing with oxen can each guide 2 pairs of oxen, or 12 animals in all: the work of an ox is the equivalent of 0.9 H P therefore, the work of 6 yoke of oxen guided by 3 men is equivalent to about 11 H P. Hence an electric machine worked by 3 men would not give as regards the man-power, a greater output than a team of animal-tractors of the same power. It has, however, one advantage, that of bringing to bear upon a single plough-share all the force of 11 H P, which is not possible when oxen are used, and is thus able to plough deep with one passage of the plough.

The S. E. M. windlass, 1921 type, although classed as a light tractor, is heavier than the DOUILHET, it weighs 3 tons and develops 35 H P, which means a little less than 100 kg. per H P and appears the minimum weight that can be combined with solidity. It works under a tension of 500 volts, and is self-working on the field.

The system of anchorage devised by ESTRADÉ, the Director of the S. E. M., is extremely simple: the inside wheels of the windlass (those on the side of the machine that is working), are furnished with cutting-disks forming, with the felly of the wheel, angle-irons of which the height is half the width of the felly. On the other hand, the cable on which the plough runs passes, before being wound on the drum, over a pulley fixed on the end of a pole coupled to the frame. This pole, which can move between 2 points, is kept in position by a pneumatic break. If a traction  $T$  is exerted on the cable the pole is drawn towards the base by a force  $F$  which opposes the force exerted by the brakes, the pole thus assumes such a position as to balance the two forces; if the traction  $T$  is increased the pole sinks further, so that a new position of equilibrium is assumed, and if the traction is sufficiently strong for the pole to reach its lowest limit, the current is cut off automatically.

By this arrangement the point of application  $O$  of the traction  $T$  varies on the axis of the windlass. The pneumatic brakes are so constructed, that whatever may be the position  $O_1, O_2, O_3$  of this point of application, the resultants  $R_1, R_2, R_3$ , of the corresponding tractions  $T_1, T_2, T_3$ , and

of the weight  $P$  always travel by the line joining the fellys of the wheels. All the force (weight and traction combined), to which the windlass is subjected thus falls on the fellys of the two inner wheels of the machine. Each of these wheels thus buries ("anchors") itself, in the ground, and presses the prism of soil between the felly and the cutting-disk, so that the windlass can only skid towards the cable in the plane  $mn$ . But in this case, the friction of the skidding is the friction of "compressed soil upon compressed soil", and it is shown by calculation, that this can only be brought about by exerting upon the cable a traction varying from 1.75 to 3 times the weight of the tractor, according to the nature of the soil.

If on the other hand the windlass were not provided with this arrangement of the pole and the cutting-disk, the skidding of the fellys (iron on soil), would take place with a traction force equal only to half the weight of the windlass.

In fact *ESTRADE'S* system of anchorage enables a tractor of  $P$  weight to stand a traction force at least 3.5 times greater than can be borne by an ordinary tractor of the same weight, which clearly means a great saving on the net cost of the apparatus. This tractor worked under extremely difficult conditions at Ondes, the dry soil being so hard that it required a force of from 2000 to 2500 kg to drag the two-way plough, though it was only ploughing with 2 shares and to a depth of 30 cm. The work was however done very regularly without any jerking.

The mechanical return of the machine is 78 %; with 2 windlasses it is possible to plough 3 hectares a day to a depth of 30 cm., and with the maximum of 100 kilowatt-hours per hectare, in the heaviest soils.

The price of the complete equipment of the two windlasses has not yet been settled, for they have not been made up in sets, but it may be estimated at about 75 000 francs.

The S. E. M. has tried to solve the difficulties connected with supplying the current on the spot and the exhibit at Ondes included a complete installation. The current is conveyed to the windlass by means of an "agricultural line", a fixed line formed of "black" stakes. These are stakes injected by a special process with a very large amount of creosote. The stakes seem to be practically permanent, for the S. E. M., has been using 20 000 for 16 years and none of them have required replacing.

Further they are non-conductors and, on "agricultural lines" at all events are able to carry the conducting wires without the use of insulators. It is also very easy to have a moveable electric switch on the ploughing ground. The initial cost of making a kilometer of the S. E. M. "agricultural line" is relatively low, and as mortgage can be spread over a great many years, the annual expense per hectare is much reduced.

In short, it was recognised at Ondes, that the question of ploughing by electricity had made considerable progress, and had passed from the theoretical to the practical stage.

The car of the automatic anchorage car devised by *BOYER* moves by means of the unwinding of a supplementary cable worked by the windlass.

Thus the car can be heavily loaded as it can be moved without hard work on the part of the men.

Various firms shewed on their stands in the Exhibition Hall different forms of electric apparatus. Among these should be mentioned, SOULE's apparatus for central supply stations for high tension lines — the motors of the Electro-Mechanical Co. — BOUT's motor-pumps — GRAMMONT's motors and china-ware — BROUSSARD and LARRES pumps. The S. E. M. exhibited their "galet de coincidence" which is already well-known and fulfils the following requirements.

1) It supplies a small low-power electric engine to fix on the frame of every machine for the home-work of the farm (root-cutter, straw-cutter, crusher etc.), and a means of working these small engines one after another, so as to increase the number of work hours of the electric force and decrease the power used.

The "galet" is an excellent means of transmitting current to such engines.

2) Provides a possibility, should there be any interruption in the system of distribution, of working by hand the low-power machines of the "galet de coincidence" which is started instantaneously with the greatest ease.

Among the machines made in the Toulouse district, the author mentions the OLIVES stacker, driven by electric engines and the LAPORT electric-lorry.

The lorry can carry 5 tons net weight and is provided with a battery of 1500 kg. accumulators, composed of 80 parts capable of supplying 250 ampère hours, or 160 volts. One charge of the battery, which costs 10 fr. is sufficient for a 65 km. run and is ample for ordinary farm transport work.

There are two types of battery, one of lead, costing 12 000 francs, and guaranteed for 2 years, and the other made of ferro-nickel costing 40 000 fr. and guaranteed for 10 years. The battery is connected with two motors of 10 HP each driving a wheel by direct contact. It is provided with 5 speeds, the highest being 20 km. an hour. The lorry in working order and fitted with a lead battery costs 45 000.

95 - **Trials of a Tractor Running on Poor Gas, in France.** — GREILSAMMER, R., in *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VII, No 32, pp 606-701. Paris, October 19, 1921.

Trials were made on September 24, 1921, at Treuillaut near Chateauroux, with a CAZES gasogene, type D. L. 30 to 40 HP mounted on a TOUTRAND-LATIL tractor drawing a three-furrow plough working to an average depth and width of 1.05 m. and 0.15 m. respectively, giving a traction of 750-800 kg.

The engine of the tractor was of vertical 3-cylinder type with a 0.105 m. bore and 0.130 m. stroke; it developed 35 HP, ran at 1 200 revolutions, usually worked on paraffin and had not been modified in any way.

On the same ground and on the same day, a similar tractor running

on paraffin drew a 4 furrow plough at the same rate, which would seem to show that the loss of power due to substituting poor gas for paraffin was not above 25 %.

The objects of these trials were to determine the time taken, the coal, wood and water consumed and to observe the working of the engine.

*Time-taken.* — The trial on Sept. 24, lasted 4 hrs. 25 min. distributed as follows :•

Charging, lighting and ventilating at start . . . . .	23 min.
Ploughing proper . . . . .	2 hrs 52 "
Time on the way . . . . .	20 "
When not-hauling:	
At starting . . . . .	4 min
During ploughing . . . . .	10 "
After cleaning the radiator . . . . .	4 "
	17 min. 17 "
Stoppage for cleaning the radiator and supplying the scrubber with water . . . . .	22 "
Getting up speed after cleaning . . . . .	5 "
	4 hrs 25 min.

The following remarks should be made as regards these different times.

1) In addition to the time spent on the ploughing proper (2 hrs. 52 min.), which includes ploughing and turning at the end of the field (length 342 m.), the machine stopped on the way and on the grassland of the farm for 20 minutes, and was not hauling for 17 minutes counting the starting and various delays for regulating the plough or tractor during the course of the work.

In order to calculate the fuel consumption per hectare, the author reckoned the amount burnt in the 2 hrs. 52 min. while the fuel and water were also used in crossing the grass-land, when the machine was unoccupied, and also during the slow combustion for 1 hr. 50 min after the trial. The figures therefore are much higher than they should be, and would only be reached under the most unfavourable conditions.

2) The charging, lighting and ventilation at the start took 23 minutes only. The time was reckoned from the moment of beginning to fill the empty gasogene until the engine began to work. The actual time taken for ventilation was 21 minutes.

3) In the course of the work, an unavoidable delay was caused by the necessity for cleaning the pipe supplying water to the scrubber, which was stopped up with seeds and impurities from the washing water which had not been filtered before use. This fact is interesting as showing that the removal, cleaning and replacing of the radiator took 22 minutes only, and in spite of the introduction of air into the apparatus, a ventilation of 5 minutes was sufficient to start the engine.

4) The slow combustion for 1 hr. 50 min. after the test made it impossible to estimate the amount of coal remaining after trial which was burnt at a pure loss during this period.

*Estimate of surface ploughed and fuel consumed.*

1) Average speed of tractor: 27.30 metres per hour			
2) Surface ploughed . . . . .	<i>total</i>	<i>per hour</i>	
	7.85 ares	25.41 ares	
3) Wood (for lighting) . . . . .	<i>total</i>	<i>per hectare</i>	<i>per hour</i>
	5.580 kg.	—	—
Charcoal . . . . .	38 kg.	52 kg.	10.6 kg.
Water . . . . .	45 litres	62 litres	12.5 litres

The oil consumption was not measured, but it appears from the statements of the drivers, that a saving of 30 % was effected.

This is probably due to the fact that there is no partial combustion of the oil used, and therefore, as the author has found, the oil remains pure and preserves its lubricating power longer.

This is one of the interesting results of the use of poor gas from the economic standpoint.

VARIOUS OBSERVATIONS MADE DURING THE WORKING OF THE ENGINE. — The cylinders and plugs when examined after working were cleaner and less soiled with calamin than in the case of an oil driven engine.

The working of the engine left nothing to be desired during the trial, it started as easily, if not more easily, than with oil.

After working alone the engine started again without any trouble when the plough was attached; when the traction resistance was increased, the engine slowed down without any stoppage. In short it worked as well in every respect as a good engine running on oil.

*Conclusions.* — The figures given above show, that the charcoal consumption of a 35 HP tractor provided with a CAZES gasogene is 52 kg. per hectare at maximum. The charcoal was bought on the spot for 0.22 fr. the kg., and the fuel cost per hectare amounted to 11.45 fr.

Under the same working conditions, the engine uses 40 litres of oil (costing about 72 fr.) per hectare.

The saving realised is thus about 60 fr. per hectare.

In other words the expense of the fuel for a tractor driven by poor gas is 6 to 7 times less than if it were run on paraffin; the amount saved being about 85 %. This saving would continue, even if the cost of fuels were to fall to pre-War prices.

It should be mentioned that charcoal can often be bought at an even lower rate, especially in the Colonies, where it is sold at a very low figure, allowing a development of motor-ploughing to a limitless extent in the future in such countries. It may be hoped that poor gas will solve the problem of finding a cheap motor-fuel for agricultural traction and gradually replace the paraffin and petrol at present used for the purpose.

Tractors can be made to run on poor gas without changing the engine and with the simple addition of a relatively small gasogene (of 1 cubic metre) of moderate weight.

96 - **Mechanical Flax-Gatherers at the Show Held at Wattignies-lez-Lille, France.** - *Génie rural*, Year XIV, No 110, pp. 21-25, figs. 2 Paris, September, 1921.

In all branches of human activity, labour is a problem of ever increasing difficulty. The scarcity of workers coupled with the high and sometimes prohibitive wages demanded, cripple all industries, and are the chief causes of the decline of flax cultivation both in France and in other countries.

Great efforts have been made to extend the growing of flax and to substitute machines for hand-labour especially in gathering the crop. At the Wattignies-lez-Lille show, which was organised by the Departmental and Regional Offices of the North, and by the Flax-Growers' Committee of France, some improved mechanical flax-gatherers were exhibited, the principal models being two constructed respectively by Messrs MARSHALL, Sons and Co. Ltd., Gainsborough, and the firm of PUSH TOMBYLL.

With the first of these machines, the standing flax is gathered by means of a row of steel combs mounted on two metal endless belts.

The comb-carriers are furnished with rollers of soft steel turning on steel rails with angle-irons fixed to both sides of the machine.

At the back end of the machine, the rails are curved so as to form cams, or fixed eccentrics.

The divergence of the mechanism of the combs on passing over the fixed eccentrics causes a raising or retarding movement that sets free the comb-cleaners; in this way the combs are freed from the flax, which is not carried above the apparatus. The combs cut the flax below the machine.

In proportion as the gatherer is drawn forward by horses or a tractor, the combs beneath the machine pull backwards. This reverse motion reduces the danger of shelling that might occur if the crop were too ripe. The action of the machine is such as to leave all the weeds standing.

The teeth of the comb are so attached that in case of accident, they can be replaced on the field itself. The comb-cleaners make a kind of collar surrounding the row of teeth that form each comb. Cams or fixed eccentrics set in motion the arms of the cleaners. The latter begin work beneath and at the back of the machine, in order to remove the flax stalks pulled up and to clean the combs.

Each comb works independently as regards gathering and cleaning.

The machine is provided with a coupling supplied with clutch and spring for engaging and disengaging the combs and the lever working the coupling is placed within easy reach of the driver.

The frame of the machine is rigid steel and has 2 driving-wheels, one of which (the interior wheel) is geared for transmitting the movement to the gathering apparatus.

The output of the machine varies greatly with the condition of the field and crop, and also with the system of traction employed.

It can pull up the flax on an area of 2 to 4 hectares per day, the amount gathered varying according to the form of traction whether by

*Mechanical Flax Gatherer.* — MARSHALL SONS & CO.

Fig. 1. — Front view.

Fig. 2. — Backview.

horses, oxen or a tractor. All the machines sold in Scotland in 1920, gathered flax at the rate of 4 hectares a day.

The machine gathers the flax in swathes 90 cm. wide. It arranges the straw neatly on the ground behind it at regular distances apart.

The gathering-mechanism can be regulated as regards height and inclination to the ground, so as to suit crops with stalks of different length and the adjustments can be made on the field.

If a small tractor is used in preference to a draught-animal, it is possible to do the work with greater regularity, and in addition, the driver is able to direct the machine better in its course through the crop. The shafts are reversible and by a simple change in position can be used either for animal traction, or machine traction. The machine weighs about 920 kg., and can pass through a gate 2.75 m. wide.

During the flax season of 1921, these machines were used in the flax fields of England, Scotland, Ireland, India, British East Africa and Italy.

Messrs MARSHALL SONS and Co. Ltd. are the sole constructors and sellers of all the machines patented by the "Fibre Corporation Limited" for the treatment of flax. These include, not only gatherers but also shellers, capsule crushers, automatic strippers and dressers. Messrs MARSHALL make a special patented crusher of their own invention for rolling flax stalks.

The machines of the firm PUSH TOMBYLL (General Agent for France of the DESCARPENTIER-PETIT Firm at Lecelles, Nord), also took part in the trials at Wattignies.

The PUSH TOMBYLL firm have made a type of flax-gatherer mounted on a binder-harvester which, by a special arrangement of the binding apparatus, makes bundles the size of a good handful; the bundles are tied with a piece of hemp and then thrown to one side.

The gathering apparatus of this machine consists in rollers covered with rubber which are fixed at an angle of 45° with the ground. The flax is fed to the rollers by rakes placed in wheels and separated by steel plates forming a triangle, and it is pulled up by the rollers which work in pairs. After passing the rubber-covered rollers, the flax is caught by wooden rollers of a special shape and falls again upon a moving plane that carries it to the binder.

By means of these new machines, the problem of the mechanical gathering of flax has been solved, and the chief hindrance to the development of flax cultivation removed.

97 - **Wind-Mill with Coupled Wheels.** — RINGELMANN, M., in *Journal d'Agriculture pratique*, year 85, Vol. II, No. 43, pp 356-357. Paris, October 29, 1921.

The diameter of the wheels carrying the metallic sails of a windmill might be supposed to be a matter of indifference dependent solely upon the amount of resistance required. In practice this is not the case and the most usual diameters of these wheels are 2.40 m., 3 m. and 3.60 m.

At the British Royal Agricultural Show held at Park Royal in 1903, out of the 19 competing engines which all raised water 60 m. and had a wheel-diameter varying from 2.40 m. to 9 m., the 6 mills which gave the best results had wheels 4.80 m. in diameter. With a wind velocity of 4.47

per second (16.090 m. per hour), the water raised by these mills represented the expenditure of 19 to 24 hundredths of HP. One model is said to have developed about  $\frac{1}{2}$  HP. The results of the competition proved, that in raising water to the height of 60 m. the best returns are obtained with a wheel-diameter of 4.80 m.

The author knows of a plant in which there are 2 independent wheels each mounted on the summit of a pier. The two piers are connected

Wind-Mill with Coupled Wheels.

half-way up by a bridge passing above a building used for various purposes and containing a wash-house.

In a windmill connected with a house in Kansas 2 wheels of the same diameter instead of being carried each on a special pier, are mounted on a large cross-bar; the latter carrying one sail and one rudder: the cross-bar turns in the horizontal plane about the upper part of the pier. The accompanying figure is taken from a photograph of this mill with coupled wheels driving a powerful pump that fills a large reservoir with water used for irrigation.

## RURAL ECONOMICS

98 - **Cost of Producing One Quintal of Grapes in the District of Asti, Piedmont.** —

DALMASSO, G., and LISSONE, in *L'Italia vinicola ed agraria*, Year XI, No. 44, pp. 686. Casalmongerato, October 30, 1921

The following calculation was made by Prof. DALMASSO and discussed with Prof. LISSONE.

Cost of making a specialised vineyard (in the district of Asti), reconstituted with American stocks, using 5700 vines per hectare, to the end of the 3<sup>rd</sup> year; 39 000 *lire* per hectare. — Cost of one vine to the end of the 3<sup>rd</sup> year, 6.85 *lire*. Depreciation and interest on capital outlay, calculating the duration of the vineyard at 35 years, 2 775 *lire* per annum.

Cultivation expenses (114 days of male labour and 91 days of female labour per hectare, amount of depreciation, interest, etc.), 6 509 *lire* per hectare. With an average crop of 70 quintals per hectare, or 1.22 kg. per vine, which may be obtained from a reconstituted vineyard, the production cost of a quintal of grapes is 91.56 *lire*, or with a lower yield, more nearly approaching the usual average of 42 quintals a year, the production cost amounts to 152 *lire* per quintal.

On making a similar calculation from data collected in the neighbourhood of Alba, Prof. LISSONE found that in the vineyards of native vines with an average yield of 52.26 quintals per hectare (allowing for an average loss of 20 % due to injury from hail and *Cochylis*), the mean production cost of one quintal of grapes is about 130 *lire*.

## AGRICULTURAL INDUSTRIES.

99 - **Extraction of Grape-Pip Oil by Means of the Dutch "Tordoir"** (1). —

GRIMALDI, L., in *L'Italia vinicola ed agraria*, Year XI, No. 42, p. 653. Casalmongerato, October 16, 1921

INDUSTRIES  
DEPENDENT ON  
ANIMAL  
PRODUCTS

The "tordoir" constructed by the "Utrechtsche Machinefabriek", of Frans SMULDERS at Utrecht (Netherlands), which gives excellent results in extracting oil from seeds in general, had not previously been used for the extraction of oil from grape-pips. At the request of the author, the firm of SMULDERS carried out experiments with grape-pips giving the following results.

The grape-pips were treated by means of several kinds of apparatus.

1) A wooden sieve, with an internal aspiration — 2) a mill (Anglo-American system), with 5 superimposed cylinders — 3) a double-walled feeder for the heater — 4) a pip heater — 5) an oil press — 6) a mural pump — 7) a filter-press with chambers, or a bag filter — 8) drivingwheels and transmissions.

The operation is carried out as follows :

The grape-pips are cleaned in the sieve, or by an aspirator that removes the dust and other impurities. They are then transported to an Anglo-

(1) See R. July-August 1920, No. 797. (Ed.)

American mill, where they are crushed to the required fineness, the meal falling into the feeder which is affixed to the heater in which the pips are heated to the required temperature. The feed also regulates the entrance of the pips that are to be treated.

Before passing into the crusher the meal is always heated to between 60° and 65° C, which can be effected by introducing a steam pressure of about 3 atmospheres into the heater.

From a small quantity of grape-pips received from Italy, 16.65 % of oil was obtained and each charge was treated in 15 minutes. Therefore 180 kg. could be treated in 1 hour.

The residue evacuated by the crusher contained 7 % of oil.

The machine used about 15 HP. The oil is collected in a vessel and aspirated by a pump which drives it into a filter-press. If it is desired to dispense with the press, the oil can be passed through a filter with bags.

By means of this small experiment, the firm of SMULDERS discovered that their machine is very suitable for crushing grape-pips. If the operation were carried out on a larger scale, the return would certainly be higher.

100 - **Paraffin from Colza-Oil.** — MAILHÉ A., in *Comptes rendus de l'Académie des Sciences*, Vol. 173, No. 16, pp. 658-660. Paris, October 17, 1921.

In a previous work, the author has shown that the decomposition of linseed oil with a mixed catalyst (copper-magnesia), results in the formation of a gas of high calorific power and also of a liquid, which after hydrogenating with nickel at 180° C forms a mixed paraffin composed of formenic and cyclic hydrocarbons with a predominance of the latter.

Most vegetable oils behave in the same manner. Colza oil was decomposed with a copper-aluminium catalyst in a copper tube at a temperature of 550° C to 650° C and incondensable gases and a liquid were produced.

The gas which is very luminous, is composed of ethylene and formenic hydrocarbons and of hydrogen accompanied by carbon monoxide and carbon dioxide.

Two fractions are easily separated from the mahogany-brown liquid, one boiling at 150° C and the other at 250° C. The residuum on being again passed over the catalyst gives a fresh supply of both products.

After treatment with a dilute solution of sodium and with water both liquids were hydrogenated with nickel at 180° C. In one experiment, at the beginning of hydrogenation with active nickel, one part of the liquid distilling at 100° C to 120° C (density 0.7584 at 23° C), only contained cyclohexanic hydrocarbons with traces of formenic hydrocarbons. This liquid was not affected by the sulpho-nitric mixture, but when decomposed with nickel, at 350° C it formed benzine and toluene which were identified by their transformation into nitric derivatives, the residual nitration liquid having a density of 0.7210 at 21° C.

Hence it seems by using more or less active nickel for the hydrogenating

(1) See *R*, Nov. 1921, No. 1169. (Ed.)

reaction, it is possible to obtain at will a paraffin composed of both aromatic and cycloformenic hydrocarbons, or else of cycloformenic hydrocarbons alone.

101 - **Development of Indigo Industry in India and Nature of Changes Occurring during Extraction** (1). — DAVIS, A. W. (Indigo Research Chemist to the Government of India). I. Notes on the Development of the Indigo Industry in Assam in Conjunction with Tea and other Crops. — II. The Nature of the Changes occurring during the Extraction of Indigo from the Java Plant (*Indigofera arrecta*). — *Agricultural Research Institute, Pusa, Indigo Publications*, No. 8, pp. 17, and No. 9, pp. 76, tables 10, figs. 11. Calcutta, 1921.

I. — DEVELOPMENT OF INDIGO INDUSTRY. — The data given show the possibilities of indigo in Assam as compared with results obtained on the present badly deteriorated planters' estates in Bihar. Growth is evidently far more luxuriant in Assam, the yield of plants per acre amounting to from 200 to 300 maunds with a percentage of indigo-tin in the leaf of 1 % as compared with 50-80 maunds and 0.6 % in Bihar.

The author gives details of the actual yields of indigo at the first Assam indigo factory at the Panchnoi Tea Estate, established in 1919. WALTON (Acting Imperial Agricultural Bacteriologist) found by making bacterial plates by the indican-agar method (HUTCHINSON) that the water was as a rule extraordinarily deficient in the indican hydrolysing types of bacteria which it has been found are essential for good steeping results.

From tests already made by WALTON it seems possible to correlate the rate of growth of bacterial plates made on indican-agar with the time of steeping required, and it may be possible to adopt a method of this kind in ordinary factory control. The time required for steeping varies according to district, but once the best time for steeping is ascertained, it should give fairly regular and constant results. Much scientific work is still needed before control measures can be effected satisfactorily.

However, a method has recently been devised by the author and tested with success at Panchnoi. The test is colorimetric and by this samples of the extraction liquor in the vats can be compared at intervals of half an hour during the steeping; whilst the extraction is improving, and *before* the optimum time has been reached, successive samples show an increasing depth of blue colour when the test is applied as described in the Appendix; *after* the optimum has been reached, successive samples rapidly lose colour owing to the destructive changes which lead to the loss of indigo.

This method should obviate to a large extent the main difficulty of working indigo in Assam, namely, the variability of the water from day to day which necessitates a different time of steeping each day.

Owing to the extraordinary yield per acre of the indigo plant in Assam, the manufacture of indigo should be extremely profitable in this province, (at Panchnoi from 24 to 37 seers have been obtained per 100

(1) See R. Oct. 1921, No. 1057 and No. 50 of this Review. (Ed.)

maunds of plant ; these estimates were based on wet-cake measurement after pressing according to the customary Bihar basis of calculation). Data are given with regard to probable profits from indigo in Assam with different yields and different selling prices, and it is clear that a remarkable profit is obtainable.

With average working, yielding 20 seers of indigo per 100 maunds of plant, an output of 200 maunds of plant per acre would yield a profit of Rs. 275 per acre and an output of 300 maunds of plant a profit of Rs. 450. With very favourable average working (30 seers per 100 maunds) the calculated profits are Rs. 475 and Rs. 750 with yields of 200 and 300 maunds of plant per acre respectively. Natural indigo produced in Assam can with favourable working displace synthetic altogether from the market.

The actual cost of working with freshly cleared lands, which need much weeding and hand labour for sowing, cultivation and harvest, worked out at Panchnoi at Rs. 125 to Rs. 150 per acre. With higher acreage the expenditure would probably be less, especially as the land becomes freer from weeds : taking Rs. 150 per acre for 150 acres the total working costs would be Rs. 22 500.

The experimental factory to work 300 acres entails a cost (including the cost of the whole factory and machinery) of Rs. 50 000 and Rs. 55 000.

The author gives an outline of the existing markets for natural indigo, quoting China as a country where there is an immediate and active market waiting to be supplied with indigo in *its proper form* ("20 % paste") similar to that supplied by German producers. In recent years China and Japan alone have taken half of the entire European production of synthetic indigotin.

In the above calculations of profits no allowance has been made for the very marked value of the refuse from the indigo steeping vats (seet) as a manure for other crops ; indigo "seet" has exceptional value as a quick-acting nitrogenous manure for developing leaf growth. The development of tobacco in Bihar has been due almost entirely to the use of "seet" as a manure. There is no doubt that its use as a manure for tea would go far to reduce the very heavy outlay on nitrogenous manures which is now necessary. It could be used advantageously on newly opened up or newly cleared tea land and considerable profits would be forthcoming before the tea comes into yielding and by growing indigo between the bushes, the soil would be enriched with nitrogen. In addition experience in Bihar has shown that "seet" is an admirable manure for sugar cane and hence the distinct advantage of growing indigo on newly opened up sugar cane estates.

The growth of flax with indigo should also be considered at the present time ; flax could be grown and manufactured in the cold weather and the indigo vats would be very suitable for the retting process, and this crop would advantageously utilise labour in the off-season. A large supply of seed could also be obtained which could be pressed for oil and cake to be utilised as manure.

II. — NATURE OF THE CHANGES THAT TAKE PLACE DURING THE EXTRACTION OF THE INDIGO. — The facts presented in this paper indicate clearly the general nature of the changes occurring in steeping and beating to extract indigo, and the development of harmful acidity which is apparently one of the principal causes of low produce and impurity. Suggestions are made with a view to general improvement from a practical working standpoint as regards:

1) The selection of favourable non-destructive types of bacteria in steeping; 2) the study of methods of establishing these in the steeping vat; 3) methods to obviate the destructive action during steeping and beating on the indoxyl of acidity developed by bacterial action.

In all the experiments referred to, whether carried out on laboratory scale or on a larger scale in the experimental vats at Pusa, a known weight of plants was taken and steeped in a known volume of water, the percentage of leaf on the plants and the percentage of indican in the leaf being previously determined. In this way the possible yield of indigotin could be calculated. Analyses were made with a view to following the progress of extraction and hydrolysis.

Typical bacterial fermentations of the indigo plant are described which show that although wide variations may occur in the efficiency of extraction and efficiency of oxidation, the general principles of the action are quite definite. Results obtained in these experiments illustrate the necessity for having a simple test to decide each day the exact time of steeping required (See Pt. I). Tables, figures and graphs, show the results obtained after fermentation with various types of water and also with distilled water. The rate of formation of acid in steeping (*i. e.* carbonic acid) varies widely in different fermentations and this has a very marked effect on the yield and purity of the resulting indigo. The necessity for control and the test recommended have been described above (Pt. I) and it is equally important to prevent the development of too high an acidity in steeping.

102 - **Changes in the Composition of Sheep's Milk during the Lactation Period; Experiments Made in Hungary.** — WEISER, ST. (Communicated by the Experiment Station of Animal Physiology at Budapest), in *Die Landwirtschaftlichen Versuchs-Stationen*, Vol. VIII, Parts 1-2, pp. 131-140, 3 tables. Berlin, November 1920.

INDUSTRIES  
DEPENDING  
UPON ANIMAL  
PRODUCTS

Experiments on two Frisian ewes kept at grass during the lactation period lasting from the middle of March to the middle of September. The animals were milked twice a day and samples of the milk were taken every month. The morning and evening milk was not mixed. The data obtained refer to the average values of the combined morning and the evening milks respectively of the two sheep. By calculating the average composition of ewe's milk during one period of lactation and comparing the values obtained with the figures given by other authors, it can be seen that these values only vary within very narrow limits, as is shown by the following Table.

*Average Composition of Ewe's milk during One Lactation Period  
as Estimated by Different Authors.*

Authors	Specific gravity	Dry matter	Fat	Total protein	Casein	Albumen + globuline	Lactose	Ash

The effect of the course of the lactation period upon ewe's milk has been studied by several authors. The most thorough investigations have been made by O. LAXA (1) and F. BAINTENER (2). In the author's experiments the sheep's milk underwent considerable changes during the lactation period.

The amount of dry matter perceptibly increased for the two first months (March and April), then remained about the same till August, after which it again increased. Between March and September the total increase was 7 %. LAXA made the same observations in the course of his experiments with the Orava breed of sheep. He found the dry matter content of their milk to be from 14.92 % to 17.35 % in April and 24.6 % in October.

In other experiments, with the Zackel breed of sheep the dry matter rose to 14.10 — 15.26 % in April and to 25.94 % in October.

In BAINTENER's experiment with Hungarian Zackel sheep the dry matter content reached 13.7 % in March and 20.23 % in September.

As regards fat, similar observations were made.

The fat content rose for the first 2 months, remained about the same for 4 months and then again increased a little in the last month.

The total increase in fat was 4.35 % (from 3.5 to 7.85 %). In BAINTENER's experiments, the average fat content of sheep's milk was 2.92 % in April and 8.14 % in September.

LAXA found that the fat content of the milk rose during 7 months from 4.27-6.25 % to 9.67 % and from 4.44-5.0 % to 9.65 %. On the other hand the changes in the dry matter and the fat content recorded by G. BIRÓ were less than those reported by the author, LAXA and BAINTENER.

(1) Cf BURR, A. and BERBERICH, F. W., Studien über Schaf-Milchwirtschaft, 1911, pp. 30-35.

(2) *Ibidem* p 31. (Author's note)

From April to August the dry matter increased from 17.57 to 20.63 and the fat content from 6.34 to 9.02 %.

The casein content varied differently from the albumen and globulin contents, for whereas the quantity of casein remained fairly constant from April to August, only rising a little during the latter month, the changes in the albumen and globulin were greater though more irregular.

The amount of lactose decreased 1.41 % as the lactation period advanced, falling from 4.83 to 3.69 %. In BAINTRER's experiments it fell to 1.13 %.

The percentage of mineral substances also underwent changes during the lactation period, rising to 0.72, in March and to 0.97 in September.

An even more marked advance of the lactation period was shown in the composition of the dry matter of the milk. The fat content of the dry matter increased greatly after the first month, and then remained about the same until the end. The amount of fat-free extract changed but little after the first 2 months. The lactose content of the dry matter however decreased perceptibly during lactation. A slight drop was also noticed in the ash of the dry matter (5.55 % in March ; 4.57 % in September).

The crude protein of the dry matter increased slowly, but continuously : 24.52 % in March ; 29.70 % in September. The changes which took place in the amount of casein in the dry matter, were similar in character, although less in degree, to those observed in the fat content (24.52 % in March, 26.60 % in April and respectively 23.93 — 24.85 — 26.91 — 27.63 — 29.70 % in May, June, July, August and September). The albumen and globulin were found to increase more than the casein (2.62 % in March. 6.23 % in September), while the amount of anides slowly diminished.

On comparing the changes taking place in the milk composition during the lactation period (1) it is found that they are much greater for sheep than for cows.

## PLANT DISEASES

### DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN

105 - **A Transmissible Mosaic Disease of Lettuce in the United States, especially in Florida.** — JAGGER, I. C., in *Journal of Agricultural Research*, Vol. XX, No. 10, pp. 737-740, pl. 1. Washington, D. C., Feb. 1921

In January 1920, Roman lettuce (variety Paris White Cos) in a field at Sanford (Florida) was noticed to be attacked by a transmissible mosaic disease, showing a yellowish discoloration along the smaller veins of the younger expanding leaves. This symptom was usually evident for a few days only, followed by a general yellowish appearance of the whole plant. All gradations of discoloration occurred, from very marked, to conditions hardly to be distinguished from the normal. Close examination usually revealed irregular blotches of a comparatively normal green colour, generally located along the larger leaf veins. The blotching varied from a few green patches barely perceptible on a yellowish leaf to numerous pronounced green spots giving a marked mottled appearance to occasional plants. The leaves of diseased plants generally seemed to be rather more wrinkled than those of normal plants. Where plants became diseased only after reaching a considerable size, the older leaves, which were fully expanded on the first appearance of the symptoms, frequently continued to appear perfectly normal, while all the younger leaves developed disease symptoms. At the same time the head lettuce (variety Big Boston) in a neighbouring field, developed a similar diseased condition. The general yellowish appearance of whole plants was frequently pronounced, but in most cases the blotching was less marked than in the Roman lettuce, and a decided mottled appearance was never observed.

In general, diseased plants were stunted. In severe cases the plants were decidedly undersized, and occasionally the leaves formed only a rosette. Usually loose heads of poor quality were formed, although all gradations of development, including occasional heads of normal size and hardness occurred. Often plants that showed marked discoloration, mottling and stunting soon after becoming diseased, seemed partially to recover later and to make a more or less normal growth with only slight discoloration and mottling.

106 - **Dry Gummosis of Citrus Trees in Sicily.** -- SAVASTANO, L., in *R. Stazione sperimentale di Agrumicoltura e Frutticoltura, Agrale, Bollettino* 41, pp. 5-7. Aci-reale, 1921.

The extraordinary drought which prevailed in Sicily in 1920, accentuated a type of gummosis which is little noticeable in normal years. This form of the disease has been called by the author "gommosi secca" (dry gummosis). It consists of a diseased condition appearing on the branches and trunks of the citrus trees, but not accompanied by any flow of gum from the cortex, being thus confined to the cambium and sap-wood. The disease spreads chiefly along the branches and trunk in a longitudinal direction. The tissues, when attacked, first become dark coloured sometimes turning almost livid. The characteristic symptom distinguishing this form of the disease from ordinary gummosis is the dryness of the affected zone. During the first period of the attack, the cortex remains green and intact, giving no hint of the existence or spread of the disease. Soon, however, it begins to wither and assumes the characteristic aspect of bark infected by this form of gummosis, becoming dry, wrinkled and somewhat darker in colour.

Dry gummosis has a greater pathological effect upon the growth of the diseased branch or trunk than the usual moist form. The ascent of the sap being interrupted, the branches and twigs begin to wither in the region of the patch of gummosis; the process first affecting the delicate growing tissue of the extremities. If the base of an otherwise healthy branch is wholly surrounded by diseased tissue, the branch slowly perishes; if the infected tissue only partially encircles it, the disease spreads from the infected part upwards, the branch withering during its progress, according to the severity of the attack.

Dry gummosis and moist gummosis may occur alternately in successive years.

In the spring of 1921, many cases of dry gummosis were observed in gardens of citrus-trees in the district of Messina, where cultivation methods have been radically changed for many years past in order to obtain "verdelli" (green lemons). The usual irrigations in these cases are suppressed from May to July; this treatment, known as "la secca," was followed in 1921 by a drought that greatly increased the severity of the disease. Liberal irrigation subsequent to "la secca," which forms part of the technique of the cultivation of "verdelli," only increased the evil by augmenting the water pressure in the interior of the tree.

An examination of several citrus gardens showed that dry gummosis is as old a disease as ordinary gummosis, but that on account of the exceptional drought in 1921, it had assumed a very severe form and thus attracted attention.

The best means of controlling this disease is systematic pruning and manuring, more ploughing and less irrigation; in short, the citrus-tree grower must adopt all the methods of treatment and of hygiene that have hitherto proved successful in the case of ordinary gummosis.

# DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

## GENERAL

107 - **Fungi of Macedonia.** — SYDOW H., in *Annales Mycologici*, Vol. XIX, Nos. 3-4, pp. 243-254. Berlin, 1921.

A list of the fungi collected by Prof. J. BORNMÜLLER in North and Central Macedonia in 1917 and 1918, and determined by the author.

As little is known about the Macedonian mycological flora in general, and the micromycetes in particular, most of the species mentioned may be regarded as new for the part of the country visited.

The following fungi are new to science: *Uromyces Hippocrepidis* Syd., living on *Hippocrepis ciliata*; *Puccinia lolii* Syd., on *Lolium perenne*, and *Aecidium macedonicum* Syd., on *Phyteuma limonifolium*.

Among the other species found, special mention should be made of *Ur. valesiacus* Ed. Fisch. which had hitherto only been known in Switzerland, but has now been observed on the same host-plant (*Vicia onobrychioides*) in Macedonia, not far from the frontier of Albania.

108 - **New Studies on the Life-History of "Malvacea Rust" (*Puccinia Malvacearum*).** — ERIKSSON, J., in *Comptes rendus hebdomadaires des Séances de l'Académie des Sciences*, 1921, 2nd Half-Year, Vol. CLXIII, No. 20 (Nov. 18, 1921), pp. 925-928.

In the present article, the author summarises the results of the researches he has been making for the last ten years on the life-history of "Malvacea rust" (*Puccinia Malvacearum* Mont).

A). Germination of spores. — His latest studies have shown that this fungus has two forms of spores which although similar morphologically, are very different from the biological standpoint.

In Sweden one of these forms appeared late in the season (Sept.-Oct.) on young plants of the hollyhock (*Althaea rosea*), sprung from seed sown in the summer (June), and also during the following autumn (August-October), on plants that had over-wintered, but only in the case of hollyhocks belonging to an infected line. To this form the author gave the name of "autumn spores".

The other form appeared some years in spring and summer (May-June), on plants that had survived the winter; the spores manifested themselves generally after an interval of three or four weeks. These are the "summer spores".

The "autumn spores" can germinate in two ways. If they find themselves immersed in water, for instance at the bottom of a drop of water, they send out long filaments which are at first slender and straight, but afterwards become bent at the extremity. The terminal, very short segments separate like conidia. If on the other hand, the spores are on the surface of a drop of water, or exposed to air saturated with water-vapour, they emit short, wide promycelia, curved like a bow and producing sporidia.

The "summer spores", however, always germinate in the same manner, and form long filaments bearing conidia.

Some of the results of experiments on the germination of the two forms of spores are given in Tables I and II.

TABLE I. — *Germination of Autumn Spores.*

Paris, 1921.

duction of the "summer spores" (for instance, in 1913 and 1914). Similarly a diseased line can regain its health if the vital energy of the fungus becomes exhausted (as in 1918 and 1920).

109 — **On the Germination of the Zoospores of Vine "Mildew".** — RAVAZ, J., and VERGÉ, G., in *Comptes rendus hebdomadaires des séances de l'Académie des Sciences*, 1921, 2nd Half-year, Vol. CLXXV, No. 25 (Dec. 19, 1921), pp. 1421-1423, Paris, 1921.

The emission and germination of the summer zoospores of *Plasmopara viticola* depend upon very limited conditions of environment.

All natural waters are not equally suited to these processes; no zoospores are ever formed in the drainage water or the water from a certain well in the neighbourhood of Montpellier. The author found no appreciable traces of copper in this water, although it came from vineyards that had been liberally treated with copper sulphate. Spring-water from a district of the Allier, where no vines are cultivated, proved equally unfavourable to the formation of zoospores, and there were irregular germinations only in water distilled in glass, or in the water of the town of Montpellier, through coming from land which is not under vines.

The inhibiting properties of the water cannot be adequately explained by differences in electric conductivity, but they can be modified by the addition of small quantities of various substances. If sulphuric acid, carbon dioxide and even a very small amount of sulphate of copper is put into the water, it frequently happens that the zoospores present will germinate.

On the other hand, germination takes place regularly in rain-water or dew, and also in twice distilled water.

The authors used rain-water in their studies of the sterilising effect exerted by various toxic substances on the zoospores of vine-mildew which were thus as far as possible under natural conditions.

All the cultures were grown in watch-glasses containing from 0.5 cc. to 1 cc. of the toxic solution and kept under a bell-glass in an atmosphere saturated with water vapour, at hot house temperature.

Each series of experiments included control cultures grown in water alone.

The results obtained from spores of the same age and in similar condition were at first somewhat incomprehensible, germination taking place in concentrated toxic solutions, and failing to do so in weaker solutions. The causes of these divergences appear to be: 1) the volume of the solution and its surface tension which only allowed the conidia (zoosporangia) to be partly immersed, or in other words, germination depends on the solution reaching the whole surface of the conidia; 2) the number of spores in each culture.

There is no doubt, that the great variations observed in the toxicity of the same substance are due to similar differences in the composition of the solutions and to the method of sowing the spores.

It was found from the experiments (over 600 in number) that germination was arrested by a  $\frac{1}{5000}$  solution of sulphuric acid in rain-water and

by copper sulphate solutions varying from  $\frac{1}{300\,000}$  to  $\frac{1}{400\,000}$ , which correspond on an average to  $\frac{1}{1\,000\,000}$  of metallic copper; a saturated solution of sulphate of lime does not prevent germination, and carbonate of sodium is only active in solutions of  $\frac{1}{8000}$  —  $\frac{1}{7000}$ .

In the case of sodium and calcium certain precautions have to be taken. Cultures kept under a moist bell-jar without any carbon dioxide remain sterile up to  $\frac{1}{70\,000}$  —  $\frac{1}{80\,000}$  in the case of the calcium solution, and up to  $\frac{1}{20\,000}$  in that of the sodium.

In ordinary air however the calcium and sodium solutions quickly lose their toxic power through the action of the carbon dioxide; this in the case of the former is shown after less than an hour's exposure, the surface of the calcium being covered with crystals of calcium carbonate.

If a 6 % lime mixture is sprayed on the leaves of a vine-stock kept for one night under a moist bell-jar there is no reaction to phtalein next day. A similar stock treated with the same lime solution immediately turns a brilliant red in the presence of the reagent; but loses its colour by the following day if the night is damp, though the litmus paper re-assumes a slight bluish tint, but as it changes with Ph. 7.07, this may indicate the end of acidity quite as well as the beginning of alkalinity.

Only a very short time, occasionally even less than a night, is necessary to neutralise perceptibly the lime in cupric mixtures. This explains their failure, if lime is the only active principle.

It is agreed that atmospheric precipitations can only dissolve extremely small quantities of copper which are quite insufficient to hinder the germination of the spores of *Pl. viticola*.

If however dew taken from the surface of leaves that have been sprayed with a slightly alkaline cupric mixture is examined, very large quantities of copper, equivalent to  $\frac{1}{10\,000}$  or  $\frac{1}{7000}$  of copper sulphate, will be found present in the clear portion. Rain water, which washes the leaves as it falls, contains according to the rapidity of its descent from  $\frac{1}{50\,000}$  to  $\frac{1}{10\,000}$  parts of copper sulphate.

In such water, no germination takes place, not only immediately after the application of the cupric mixture, but even when 1, 2, 7, 9, 10, 11, 14, 15, 16, 20 days have elapsed, and after successive precipitations of 19 mm., 4.53 mm., 1.0 mm., 0.5 mm (dew), 19 mm., 1.11 mm. 2.0 mm., 0.4 mm. (dew), 41 mm., 4.92 mm., 8 mm., 1.8 mm., 0.2 mm (dew). This further shows how well cupric-calcic sprays adhere to the leaves. It required torrential rains of 41.4 mm. and 92.8 mm. to remove the

greater part of the copper, and the small quantity left was sufficient to render the dew sterile.

To sum up: calcium is too soon affected by the carbon dioxide of the air (with the formation of calcium carbonate), to be practically effective. Cupro-calcic mixtures resist for a prolonged period the action of rain and dew, but enough copper is in most cases washed off to make the water an unsuitable medium for the germination of the zoospores of the "mildew".

110 — **Kanota Oat Var. Resistant to Rust and Smut in Kansas, U. S.** — See No 35 of this Review.

RESISTANT  
PLANTS

111 — **"Formosa", Spanish Vine not Attacked by "Mildew" in Italy.** — DIANCINI, C., in *Giornale viticolo italiano*, Year XLVII, No 49, p. 488. Casale-Monferrato, December 1, 1921.

At Ceccano in the Province of Rome, the Spanish vine "Formosa", which bears excellent table-grapes, proved so resistant to mildew in 1921, a year when this disease was exceptionally severe, that it may almost be regarded as immune. In fact where it has been left untreated, as a control among a number of other varieties, the Formosa has not been touched by "mildew" and has remained green and luxuriant.

112 — **Copper, the Active Principle in Sprays.** — FENZES-DIACON, in *Le Pro grès Agricole et Viticole*, Year XXXVIII, No 52, pp. 611-612. Montpellier, December 25, 1921

MEANS  
OF  
CONTROL

VILLEDEU believed that his laboratory experiments with basic copper mixtures furnished sufficient proof of the non-toxic action of the copper, and therefore concluded that the anticryptogamic effect of these compounds must be due solely to the basic character of the medium.

He therefore advised that the usual mixtures should be replaced by a compound containing a large amount of lime, and hence very basic, in which the secondary part of fixative on the vine shoots should not be sulphate of copper, an expensive foreign product, but sulphate of aluminium which can easily be supplied at lower cost by French industry.

VILLEDEU now fully recognises the complete failure of his formula which was tested by experiments carried out in vineyards in various districts of France, but in his recent communication to the Académie des Sciences he is still of opinion that the efficacy of alkaline cupric mixtures in the control of "mildew" is to be attributed to their basic character, and not to the action of the copper compounds.

The author considered that the toxic effect of the copper in these sprays was clearly demonstrated by MANCEAU'S comparative experiments with alkaline Bordeaux mixture and VILLEDEU'S mixture. From these trials made in the open vineyard, MANCEAU draws the following conclusions. "Although the 1921 outbreak of "mildew" was not severe, VILLEDEU'S mixture proved of little use but the application of Bordeaux mixture kept the leaves healthy and insured a vigorous growth."

A convincing proof was obtained in the course of these experiments by adding 100 gm. of copper sulphate to a VILLEDEU mixture containing 5

kg. of lime, for the anticryptogamic action of the compound was found to persist throughout the whole vegetative period.

It is necessary, in order to realise the full significance of this experiment, to explain that the addition of so small a proportion of copper sulphate in no way altered the basic character of the mixture.

In fact, a little of the excess lime went to form a sulphate, thus setting free an equivalent amount of copper hydrate of the same basicity, and yet although the caustic property of the mixture was lessened, since copper hydrate is much less soluble than lime, it was still efficacious against "mildew."

Thus, by the addition of a little copper sulphate, which was not sufficient to alter the basic character of the mixture, the vanished anticryptogamic action re-appeared; is it due to the basic function that has not been changed, or to the copper? The author thinks there remains no shadow of doubt that copper compounds actually possess the efficacy against "mildew" that has been attributed to them as a result of long practical experience.

113 - **Experiments in the Use of Salts of Mercury in the Anticryptogamic Treatment of Seeds.** — GABIT, W., in *Zeitschrift für anorganische Chemie*, Vol XXXIV, No 91 pp 567-588 Leipzig, November 25, 1921

In the anticryptogamic treatment of seeds, use has hitherto been made either of the mineral salts of mercury (usually corrosive sublimate), or of complex organic mercurial compounds. Whereas in the presence of sodium or of ammonium sulphide, the mineral salts liberate mercury, the complex organic mercurial compounds are not acted upon at all, or else only to a very slight extent by these two salts, they also differ from bichloride of mercury in giving no precipitate with albuminoids so that they have no corrosive effect upon the seed, nor do they hinder its growth, while according to some accounts, they seem to have a good effect upon the yield.

The simplest organic compound of mercury is the cyanide; it is more efficacious in conferring immunity than the more complex compounds. By its use, the development of *Helminthosporium graminum* (1) can be prevented, a result never attained with the sublimate. The mineral salts of mercury, especially the sublimate, were introduced into practical agriculture by HILTNER in 1906, and used combined with copper sulphate under the name of "fusariol" for the treatment of seeds. HILTNER and his fellow-workers also tried to use various other mineral preparations of mercury. The employment of complex mercuric salts is of more recent date; they were first introduced in 1913 by RICHEM, while REMY adopted chlorophenolate of mercury for cereals attacked by *Fusarium* spp; this compound is the essential ingredient in "Uspulun." Another complex organic mercurial salt, cyanomercuricresolate of sodium, is present in "germisan", a very active but slightly poisonous anticryptogamic

(1) See R Dec 1921 No 1295. (1 d)

remedy; another substance employed in treating seeds is called "fusafine". It contains 20 % of corrosive sublimate, kitchen salt, sodium sulphate, and an azoic colouring matter.

- 114 - ***Aspergillus varians*, a Mucedinea Parasitic on Maize, in Italy.** — CIPERRI, R., in *Rivista di Patologia vegetale*, Year XI, Nos. 7-8, pp. 89-93. Pavia, October 29, 1921.

DISEASES  
OF VARIOUS  
CROPS

The author records the clearly parasitic behaviour of *Aspergillus varians* Wehm — hitherto only known as a saprophyte -- which was found frequently, in 1921, on the caryopsids of maize at Petriolo (Prov. of Macerata). All or nearly all the infected ears came from plants cultivated on the low-lying, damp, foggy fields situated along the course of the Cremona, where owing to the situation of the cultivated slopes and the thick shade made by the willows and poplars growing in abundance on the banks of the stream, there is very little sunshine.

The maize-plants were poorly developed, having small imperfect heads that ripened late and remained always damp even when ripe. The fungus confined its attacks almost exclusively to the seeds at the top of the cob which as being the least protected by the bracts are the most exposed to parasitic attack. These caryopses are always attacked in the part that is free from the rachis, they are much smaller and softer than the others, become discoloured, and ripen later than the healthy caryopses on the same head. The seeds of plants grown in dry high places were never infected by *Aspergillus varians* unless other causes, such as cracks exposing the starchy contents, facilitated its attack.

Another Mucedinea, *Cephalosporium Acremonium* Corda, has been found parasitic on *A. varians*.

- 115 - ***Macrophoma flaccida*, a Deuteromycete Causing Deterioration in Dried Grapes in the Marches, Italy.** — CIPERRI, R., in *Rivista di Ampelografia*, Year II, No. 11, pp. 164-166. Leghorn, November 1, 1921.

In the Province of Macerata, and in nearly all the Marches, it is the custom to keep fresh grapes for domestic consumption. The ripe grapes used for the purpose are gathered at the time of the vintage and the bunches are hung on reeds suspended from the ceiling of a cool, well-ventilated room, a cellar on the ground-floor being generally chosen. The grapes thus treated keep well until after New Year's Day. Those chosen for keeping are always white, such as "Verdicchio," although occasionally French Muscat and "Zibibbo" are used. Under normal conditions, grapes kept in this way shrivel and assume a colour varying from amber to brownish yellow, having in short all the characters of dried grapes.

In 1921, the berries taken from a considerable quantity of dried "Verdicchio" were of a violet brown colour, shrunken and soft; their surfaces were covered with small blackish pustules with a white spot in the centre emerging from a brownish-yellow patch of limited extent.

Microscopic examination revealed the presence of fungus fructifications (pycnidia and spermogonia) belonging to the agent of the alteration identified as *Macrophoma flaccida* (Viala and Ravaz) Cav., a deuteromycete

hitherto found only on grapes left hanging on the vines after the vintage, and hence regarded as of little practical importance.

On all the bunches in the vineyard where the grapes had been gathered, dark-red berries had often been observed which were probably attacked by the form of "mildew" known as "brown rot." Two different kinds of mycelium were, however, found on the grapes examined, one of which the author attributes to a "mildew," and the other to *Macrophoma flaccida*.

A careful inspection of the "Verdicchio" grapes at the place where they were dried showed that nearly all the berries of the suspended bunches were infected. The distribution of the diseased grapes in each bunch appears to be due to chance; the rest of the berries were pale-green, or golden-yellow, and therefore obviously free from "brown-rot."

As regards the deterioration from the agricultural standpoint, little serious damage is to be feared from the deuteromycete which behaves as a saprophyte. It is however self-evident that for grapes to keep well, they must be immune from all disease, and in the case in question, from "mildew". Therefore the control of *Macroph. flaccida* resolves itself into the control of the "mildew".

116 - On the Cankerous Tumours of *Diplodina Castaneae* Observed on the Chestnut-Tree in France. — DUFRENOY, J., in *Comptes rendus hebdomadaires de la Société de Biologie*, Vol. LXXXV, No. 36, pp. 1059-1061, 3, figs. Paris, 1921.

When a plant is attacked by a parasite, the manner, degree and results of its reaction depend essentially upon the time that the pathogenic agent and its host are able to co-exist.

This fact is clearly shown in the case of chestnut trees attacked by *Diplodina Castaneae* ("Javart"). The parasite kills the cambium cells, causes hypertrophy and hyperplasia in the active cambium some little distance off, and induces many thyloses in the vessels of the deep-seated wood.

If the victims are young chestnut poles, necrosis invades the cambium of the wound-callus forming round the first seat of infection, the disease spreads faster than the callus grows, and death rapidly ensues owing to the destruction of the ring of cambium.

On a tree trunk cicatrization proceeds more quickly than the destruction of the cambium, leading to the formation of great pads of tissue formed of overlapping scales. All that is required for the continued growth of the canker is that a certain number of the cambium cells should be protected by the suberised layers continually being formed in the phelloderm. This very sinuous barrier describes curves around the pericycle fibres which become delignified, while the more or less swollen membranes in the neighbouring parenchyma fix the lignin.

117 - A Wide-Spread Attack of *Rhytisma acerinum* Observed on the Leaves of the Common Maple in the Marches, Italy. — CIFERRI, R., in *Rivista di Patologia vegetale*, Year XI, Nos. 7-8, pp. 93-95. Pavia, October 29, 1921.

It has been noticed of late years, in the Province of Macerata, that the leaves of the Common Maple (*Acer campestre*) — grown in rows in the

fields to serve as supports for vines — fall prematurely, a few being shed at first, and a larger quantity a little later. Further a certain number of maple-trees wither and finally die. Much injury is thereby caused to the vines, as the soil is disturbed by the up rooting of the dead tree and the planting of a new one. The maples that survive become completely defoliated. The leaves, although not of much value are still useful to the agriculturist especially in seasons when forage is scanty and they are the sole product of these trees.

As a result of a visit to one of the places where the disease was most prevalent, viz. the low-lying, damp, foggy ground along the bank of the Cremona, it was found, that the leaves of *A. campestre* were attacked by the pycnidial form (*Melasmia acerina* Lév.) of *Rhytisma acerinum* (Pers.) Fr.

The disease caused by this fungus known as "Croste nere delle foglie dell'acero," which is usually of little or no importance in Italy, had broken out in the form of an actual epidemic in the district visited.

The severity and wide-spread character of the attack was not only due to the fact that the fallen leaves were not collected and burnt — the only way of destroying the fungus, for anticryptogamic mixtures have no effect upon it — but also to the continual damp of the environment.

In the same zone were observed, *Rhyt. punctatum* (Pers.) Fr., also on the maple, but more rarely, and *Rhyt. salicinum* (Pers) Fr., under its pycnidial form (*Mel salicina* Tul.) on the leaves of *Salix viminalis*. Willows growing in dry places were not attacked by the last fungus.

118 — ***Cenangium piniphilum* n. sp. Discomycete Injurious to *Pinus ponderosa* and *P. contorta*, in the States of Idaho, Washington and Montana.** —

WEIR, J. R., in *Phytopathology*, Vol. XI, No 7, pp. 294-296, figs 2, pl. 1 Lancaster, Pa., 1921.

A new species of Discomycete designated by the name of *Cenangium piniphilum* was first collected at Boulder (Montana) on *Pinus contorta* on June 8, 1915. Since then it has been found in abundance in the lake region of northern Idaho, where it attacks *P. ponderosa* and *P. contorta*. This type has been collected on a 15-year old tree of *P. contorta* at Priest River (Idaho) in the Kaniksu National Forest on May 12, 1920. The species is common throughout northern Idaho, eastern Washington and western Montana.

This fungus, which is of considerable forestal importance, attacks *P. ponderosa* and *P. contorta* between the ages of 5 to 25 years or more. Infection usually occurs at the nodes, less frequently on the internodes, but may eventually spread throughout the entire length of the stem. The mycelium penetrates the cortex, phloem and wood and causes canker. The cambium is killed, preventing any further growth in the thickness at the point of infection, and with each year's increment the outline of the tree in cross section becomes more irregular. The penetration of the mycelium into the cortex, phloem and wood causes the exudation of large quantities of resin on the surface of the canker which runs down the bark very conspicuously. The dark brown much-branched mycelium follows

chiefly the medullary rays in the wood and gives it a greyish or bluish-black colour which resembles *Ceratostomella pilifera* (Fr.) Wint. This colour may extend to varying depths or entirely through the trees in the case of two oppositely arranged cankers. The colour which always indicates the presence of mycelium may extend from one canker to another up and down the tree and is very conspicuous in longitudinal section. Brownish-black deposits in the various cells especially in the resin channels and medullary rays intensify the colour. The mycelium develops both in the cells and in the intercellular spaces. The apothecia are formed on the dead bark of the canker and vary in size according to the age of infection. The fact that infection usually occurs at the branch whorls, indicates a natural weakness at this point, and should not be attributed to wounds. Wounds caused by various agents are however a source of infection, and this has been demonstrated by experiments. The transfer of spores to incisions in the bark of young trees has always given rise to infections. When these occur at the base of the branches, they spread to the main trunk, frequently involving the entire circumference at this point. The number of cankers on a single tree is in some cases limited only by the number of whorls. A 15-year old tree may have as much as ten or more separate and distinct cankers. All these cankers may be united internally by discoloured wood. A thin ridge of tissue winding from one canker to another may be the only part which remains intact.

Although the fungus grows readily in artificial media, it has not yet been induced to form apothecia. The mycelium on artificial media breaks up into conidia, a condition not observed in nature.

The fungus thrives best in dense, moist stands.

119 - **The White Pine Blister Rust (*Cronartium ribicola*) found in Pennsylvania** (1). — *Weekly News Letter*, Vol IX, No. 15, p. 4. Washington, Nov. 9, 1921.

For the first time since the white pine blister rust aecidial form *Pedidermium Strobi* Kleb. was discovered in America, currant and gooseberry bushes were found to be attacked in Pennsylvania (Wayne Co.) in the autumn of 1921.

Although some blister rust has been noticed on pines in Pennsylvania these plants had been brought from Europe in diseased condition and were destroyed immediately.

120 - ***Trametes Pini* in Old Stands in the Joux Valley, Switzerland.** — PILlichODY, A., in *Journal forestier suisse*, Year LXXII, No. 12, pp. 223-226. Berne, Dec. 1912

*Trametes Pini* is a much less well-known parasite of pine-trees than *Tr. radiciperda* (= *Fomes annosus*), for it occurs more rarely and as it were accidentally, whereas *Tr. radiciperda* is nearly always present in plantations whether on the plain or the mountain especially where the soil is heavy. This fungus attacks by preference young stands, whereas the "red rot" (*Tr. Pini*) is a disease of adult trees. Infection takes place

(1) See R Nov. 1921, No. 1193 (Ed.)

through wounds in the trunk and especially through broken branches. Quite young trees are protected by a copious flow of resin, but this becomes less as the pine grows older, so that the fungus mycelium is able to penetrate into the interior of the trunk.

*Tr. Pini* develops chiefly in the central portion of the trunk and destroys the wood that has reached a certain age and is no longer full of resin. The disease which usually starts from a rotten branch advances both centrifugally (from the centre to the periphery) stopping when it reaches the young layers of wood which are still impregnated with resin, and ascending and descending vertically. Thus the middle of the trunk is the part chiefly attacked. It frequently happens, that a tree is quite sound at the level at which it is felled and also at the top, while the intermediate portion is so much decayed that nothing remains but the bark and a thin layer formed of some of the annual rings which insure the circulation of the sap.

As a rule, the presence of the disease is revealed by the appearance of the fungus fructifications in the form of largish brown brackets developing along the trunk usually at the place formerly occupied by a broken branch through which the disease had gained entrance. These brackets only appear when the malady is already far advanced.

Sometimes in place of the bracket, yellowish-brown crusts form that seem to creep up the lower surface of certain withered branches and thus betray the presence of the disease, being easily visible in a good light from the foot of the tree. It appears that the bracket and the crust never occur together, one or other form being assumed by the fructification.

In the forests of the Risoud mountains as in many old stands of the Joux valley, where *Tr. Pini* is relatively common, the spreading bracket form seems to be unknown and the fungus appears to manifest itself solely by the formation of crusts that sometimes cover a large part of the lower surface of the branches and attain considerable thickness. The bracket form of fructification only occurs under the axils of certain branches or in the place of branches that have disappeared, but the fructifications remain small and project little from the surface, being more like triangular or heart-shaped crusts slightly thickened and arranged on the trunk in the order of the fallen branches.

The relatively serious injury to the forest of the Joux valley caused by *Tr. Pini* is due to the great age of the trees forming many of the stands. Most of the large forests of the valley are composed of trees between 300 and 400 years of age, while in the other woods of the district individuals from 200 to 300 years old are still common. Apart from the great age of the trees and their consequently diminished powers of resistance due to reduced resin production, it is easy to understand that a disease which has been developing in a trunk for 1, 2 or even 3 centuries must necessarily have caused advanced decay in the tissues of its host. In crossing the Risoud valley a tree trunk may often be seen almost entirely reduced to a powdery mass not unlike tobacco in appearance. Hence the term "snuff box" or "tobacco plant," applied by the foresters and timber-merchants of the district to trees that have been severely affected by the

disease, and owing to the state to which they have been reduced by the prolonged attack of the fungus, are judged on felling to be useless and too decayed even for fire-wood.

121 - *Phomopsis Pseudotsugae*, Deuteromycete Parasite of *Larix leptolepis* and *Tsuga Albertiana*, in Scotland (1). - *Transactions of the Royal Scottish Arboricultural Society*, Vol XXXV, Pt 1, pp 73-74. Edinburgh, Sept. 1921.

In the autumn of 1920, symptoms of a disease on stems of the Japanese larch (*Larix leptolepis*) were noted in Bowmont Forest, (near Kelso). At that time it did not seem to be of a serious nature. The fungus appears to be identical with *Phomopsis Pseudotsugae*.

As a result of the examination of the specimen from Bowmont Forest Dr. M. WILSON has stated that the Japanese larch is without doubt attacked by this fungus, the first record of *Phom. Pseudotsugae* on *L. leptolepis*.

During May 1921, the fungus was found on the dead leading shoots of young trees of *Tsuga Albertiana* in Fifeshire.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS

122 - On the Subject of Myrmecophily. - DI WU DI MAN, L., in *Comptes rendus hebdomadaires de la Société de Biologie*, Vol LXXXV, No 32, pp 844-876. Paris, November 12, 1921.

On several occasions, the author has asserted that myrmecophily exists among plants, and has drawn attention to the fact that this association is rarely a case of true symbiosis, but rather one of parasitism. This parasitism would often seem indeed to be of an accidental character, for it is not always indissolubly connected with a specific type.

A certain number of biologists regard myrmecophily as a means of defence for plants, but many naturalists ridicule this statement, and, although they may not be right in every case, it must be recognised that ants are frequently no protection to their host.

J. MASSART, who regards the plants and ants association as a means of protection, classes myrmecophilous plants in 4 groups :

plants with nectaries Ex: *Vicia*

» » dwelling places for ants Ex: *Miconia*

» » dwelling-places and nectar Ex: *Balschia*

» « nectar and albuminoid substances Ex: *Cecropia*, *Acacia*.

The author does not however think that these cases are exhaustive, for he has frequently seen ants installed on a plant without any special attraction such as the presence of cavities, or nectaries.

In the Congo, plants are to be found bearing on their aerial parts small ant-nests which have no connection with the ground. These plants do not appear to benefit in any way from the presence of the ants, which cause them to be infested by coccids. The ants, which in most

(1) See also *R.* Jan 1921, No 110, and *R.* March 1921, No 345. (Ed.)

cases are certainly responsible for the arrival of the coccids, construct around them kinds of nests made of plant debris bound together by a cement. Within these dwellings the coccids find shelter and obtain food from the tissues of the plant, while their secretions serve to nourish the ants. The association ("plants and ants") in this case is reduced to a species of indirect parasitism.

The author recently observed similar aerial ant-nests on the branches of the *Tilliacea*, *Grewia subargentea* n. sp. This plant cannot properly be classified in one of the groups proposed by MASSART, for though its petals are provided with nectiferous glands, they do not seem specially to attract the ants.

The plants of *Gr. subargentea* on which the ant-nests were discovered came from Avakubi and Beni, where they were collected by Dr J. BEQUAERT; they formed liane like shrubs growing on the banks of streams. The ant-nests were localised on the stems, especially in the axils of the leaves, round the peduncles, and petioles, and very often in the inflorescences around the points of their ramification.

Myrmecophily seems to be accidental in the case of this *Grewia*, for specimens of the same type of plant but coming from other places between Masisi and Walikale, Nala, where they were gathered in the forest, were free from these aerial ant-nests.

This would seem to support the theory of BUSCALIONI and HUBER who believe that myrmecophilous plants grow on land subject to flooding where the ants, as they cannot build an ant-hill on the ground, seek a refuge out of reach of the water.

The author states again that he considers myrmecophily to be a very common phenomenon among plants, but not to be explained by any single theory.

Most plants could become the supports of ant-nests, and be ranked among the ant-loving species. These nests are, as has already been said, stables in which the ants keep coccids, in order indirectly to obtain part of their food at the expense of their host. In the opinion of the author myrmecophily would appear to be an association which is often accidental, and very one-sided in its advantages for it always ends in doing injury to the plant.

123 - **The Effect of Phylloxera on the Quality of Grapes.** — SANNINO, F. A., in *Rivista di Ampelografia*, Year II, No. 11, pp. 169-170, Leghorn, November 1, 1921.

In the district of San Gervasio, in the Commune of Neive, Province of Cuneo, a vineyard attacked by phylloxera has for two years been treated with carbon disulphide in the hope of enabling as many vines as possible to bear grapes. Year after year, the weakest vines, which already produce but little fruit, continue to wither and are uprooted before they die.

The following results were obtained from the analysis of two samples of grapes gathered on September 25, 1921, the one being taken from a luxuriant productive Barbera vine, and the other from a plant of the same

variety, but evidently suffering from phylloxera, as was shown by its weakly appearance and poor yield.

*Composition of the Must from Barbera Grapes.*

	Not attacked by phylloxera	Suffering from phylloxera
Sugar . . . . .	gm. 226 ‰	gm. 215 ‰
Tartaric acid . . . . .	" 12.5 ‰	" 12.3 ‰
Colour . . . . .	very bright red	less intense red

If the season had been less favourable to the ripening of the grapes, the author believes that the differences would have been greater, as they were in vineyards attacked by phylloxera which had not been treated with carbon disulphide.

The author states that he had heard it said for many years that phylloxera is a cause of deterioration in wines. He obtained a confirmation of this theory in August 1921, when he examined a sample of choice wine made from the grapes of Sauvignon and Sémillon. This wine, which came from a vineyard where the phylloxera had taken such hold that all the vines have now been uprooted, had become a totally inferior product.

Whenever it is necessary for special reasons to preserve a phylloxera infested vineyard, in order not to lose the large returns it brings in, it must be treated (as is done in Champagne) with carbon disulphide and manured with chemical fertilisers. The former lessens the injury wrought by the insect; while the latter stimulate the vine and increase its productivity.

RESISTANT  
PLANTS  
MEANS  
OF  
CONTROL

124 — **Wood of *Pterocarpus* Resistant to White Ant.** — See No. 51 of this *Review*

125 — ***Drosophila rubrostriata* and *Phora Chlorogastra*, Diptera Recorded as Parasites of the White Cabbage Butterfly (*Pieris brassicae*), in France.** — BONNAMOUR, S., in *Bulletin de la Société entomologique de France*, No. 15, pp. 217-219 Paris, 1921

During the summer of 1921 a small field of cabbages at Saint-Genis-Laval, in the neighbourhood of Lyons, was destroyed by a large number of the caterpillars of the White Cabbage Butterfly (*Pieris brassicae*).

From these caterpillars were reared numerous specimens of *Apanteles glomeratus*, and of the tachinid *Compsilura concinnata*, as well as a fair number of small Diptera. Among the latter VILLENEUVE recognised *Drosophila rubrostriata* Beck, and one individual of *Phora chlorogastra* Beck.

*D. rubrostriata* was first recorded in the Canaries, and was carried to the Pasteur Institute by bananas imported from those islands to serve as food for the monkeys kept at the Institute. It is also found in tropical Africa.

The representatives of the family *Drosophila* live on decomposing

organic matter of either animal or plant origin. Their parasitism on the caterpillars had not before been recorded. The observations so far made seem to show that *D. rubrostriata* is able, no doubt by simply depositing its eggs, to bring about the decomposition and liquefaction of the Cabbage Butterfly caterpillar, while on the other hand *C. concinnata* causes it to dry up.

*Ph. chlorogastra* is a rare southern species reported from Ragusa; it appears to have become acclimatised like *D. rubrostriata* in the Lyons district. The fact that these two Diptera are parasites of *P. brassicae* was however hitherto quite unknown.

126 — The Introduction into France of *Aphelinus mali*, the American Parasite of the Woolly Aphis of the Apple-Tree (*Eriosoma lanigera*) (1). — MARCHAL, P., in *Comptes rendus des séances de l'Académie d'Agriculture de France*, vol. VII, No. 28, pp. 619-625. Paris, 1921.

On June 4, 1920, the author received from the Head of the Bureau of Entomology of the Department of Agriculture of the United States some branches of apple-tree covered with the parasite *Eriosoma lanigera* Hausm. (woolly aphis). All the aphids were attacked by a small Chalcid Hymenopteron of American origin — *Aphelinus mali* Hald., which in its larval stage, is an internal parasite of the Aphis. Some deformed elm shoots in the shape of rosettes, containing individuals of *E. lanigera* that had been killed by the above-mentioned Hymenopteron, were forwarded at the same time.

Between June 10 and 19, this material furnished rather over 100 adult specimens which formed the first generation of *A. mali* reared in France. Most of them were collected in muslin bags, and distributed among the apple-trees in pots infected by *E. lanigera* at the National Agricultural Institute in Paris.

The second generation of the Hymenopteron, which was necessarily limited owing to the conditions of captivity in a confined space, began to appear on July 1, and continued hatching out until July 28. From this date, the rearing of the insects in Paris was gradually given up and the adults of *A. mali* that had been obtained were despatched in tubes and in muslin bags to three different centres, Antony (Seine), Montargis (Loiret) and Rouen.

By the end of September, five generations composed of thousands of individuals had succeeded one another at the breeding-stations, so that the number of centres could be increased in view of the multiplication of the species. Colonies were made at different points in the vicinity of Paris, and consignments forwarded to the Entomological Stations of Bordeaux and of Saint-Genis-Laval near Lyons. *A. mali*, in the larval or nymphoid stage passed the winter in the open, under the best conditions, in individuals of *E. lanigera* which succumbed to its attacks and

(1) See also R. June 1921, No. 692. (Ed.)

were recognised by their black colour. The eggs of the Chalcid began to hatch out at the end of March 1921.

As a precaution and in order to avoid any risk of destruction, the hymenoptera had generally been reared in 1920 within sheltering muslin bags.

In 1921, these bags were only used in the formation of new centres, the author himself adopting dispersal cages. Two such cages were made at Antony on his own estate, one of them covered a plantation containing 20 young apple-trees (Paradis) which had been intentionally placed very close together. They were infected with *E. lanigera* in the spring, and later furnished with a liberal supply of *A. mali*. The other cage was attached to a large espalier apple-tree infested with *E. lanigera* on which *A. mali* had begun to breed either in muslin bags or unprotected during the preceding year.

The cages are covered with a gauze coarse enough to allow the escape of the insects that had hatched on the boughs, but sufficiently fine to protect them against *E. lanigera*, and also *A. mali* during their larval and nymphoid stages.

Simple gauze bags used on a smaller scale proved of great value in establishing breeding centres.

By this means the author obtained from the time the 2nd generation were hatched in the spring, hundreds of thousands of *A. mali* which dispersed themselves throughout the garden and extended their boundaries, generation after generation, to such an extent that at the present time the estates adjoining the author's property are full of these Hymenoptera. They have been found breeding in places away from the main roads and tree screens within radii of 300 to 400 metres around the original centre of dispersal. A large cage 4 m. in height has been placed over two young apple-trees growing in the open near Bourg-la-Reine, where the progress of dispersal can also be well studied. Other similar cages have been set up in different places, notably at Montargis and Rouen.

Finally, owing to the large supply of material obtained in 1921, it has become possible to send boughs attacked by woolly aphids and infested with the parasite to many Stations: Orleans, Nantes, Angers, Rennes, Alençon, Noyon, Pont-de-l'Arche, Havre, Toulouse and also to many communes in the neighbourhood of Paris (Châtenay, Plessis-Piquet, Fontenay-aux-Roses, Versailles, Brétigny, Villejuif, Saint-Maur, Maison-Lafitte, Livry and Montmorency). It is almost certain, that the latter colonies will not all survive, but experiments made at Antony and Bourg-la-Reine have proved the possibility of breeding and dispersing *A. mali*, and it nows appears, that its acclimatisation throughout France and in the various countries of Europe is but a question of time.

As regards the practical effects of its acclimatisation all that can be said for the present is, that the useful part played by *A. mali* is clearly demonstrated by the enormous number of woolly aphids destroyed by it (as is shown by their black colour) which in summer cover the apple-branches in a well-established centre such as that of Antony.

As long as the buds of the apple-tree are growing rapidly, the woolly aphid multiplies faster than *A. mali*, but when the growth of the tree stops in the summer, *E. lanigera* increases more slowly. *A. mali* then contributes greatly to hasten its decline, supplementing the efforts of the native predatory insects whose efficacy varies according to the year and the place.

The author mentions facts, which he has himself observed, connected with the life-history of the Hymenopteron.

- 127 - **Economy in Hydrocyanic Fumigation.** - SCHIERHOLZ, C., in *Oesterreichische Chemiker-Zeitung*, Year XXIV, No. 22, p. 166, Vienna, November 15, 1921.

When hydrocyanic fumigation is carried out at low temperatures, only from 80-84 % of the hydrocyanic acid is liberated in 3 or 4 hours, the rest, 16-20 %, remaining in solution. Thus, in a warehouse (mill), of which the cubic content is 33 000 m<sup>3</sup>, in order to obtain a concentration of 1 % in volume of hydrocyanic acid, 3,30 m<sup>3</sup> would be needed, and calculating the amount remaining in solution, 200 kg. of cyanide of sodium, or 270 kg. of cyanide of potassium, would be required; this means 800 gm. of the latter salt per 100 m<sup>3</sup> of empty space. The present prices of cyanides make it worth while trying to find some way of reducing the amount used. It must be remembered in this connection, that the toxic action of hydrocyanic acid, like that of carbon monoxide, is due to its asphyxiating property, and that the chief antidotes are oxygen and permanganate. For this reason, an attempt was made to decrease the oxygen content of the air, either by using a solution of pyrogallol acid, or by burning vegetable charcoal. In this way, it has been found possible to reduce the oxygen of the air by 15-20 %, which is sufficient to render the action of the accumulated hydrocyanic acid 4 times as efficacious, and hence to reduce the consumption of cyanide by that amount. In 4 to 5 hours, all the insects and their eggs are destroyed and after one hour's ventilation, the air has become normal.

- 128 - **Insects Injurious to Lima Bean (*Phaseolus lunatus*) in Egypt.** See No. 37 of this Review.

INSECTS, ETC.  
INJURIOUS  
TO VARIOUS  
CROPS

- 129 - **An Undetermined Dipteron Injurious to Lucerne, in France.** - DELNAIFFE and COILLÉ, in *Journal d'Agriculture pratique*, Vol. II, No. 11, p. 313, figs. 2. Paris, Oct. 15, 1921.

During the course of experiments carried out in the experiment fields at Carignan for the purpose of determining the comparative early maturity of different types or kinds of lucerne, the authors had occasion to notice a malformation of the flowers of this Leguminosa which rendered them quite unrecognisable.

This deformity was due to the hypertrophy of the lower part of the leaves of the corolla which caused the tips to curve slightly inwards, giving the flower a globular appearance, its petals being arranged so as to form a cone. The malformed blossoms had a very long flowering period and retained their freshness for an unusual time. They were produced

for over three weeks and remained unopened until they withered late in the season.

It was curious to see on the same inflorescence, in spite of its centrifugal development, normal spiral pods at the top where the flowers were normal and malformed flowers at the base still in the flowering stage.

Under the pressure of the corolla that has grown vesicular, the calyx becomes distended and splits on the back of the flower where it remains wide open, whereas the five subulate teeth terminating the calyx all lie on the ventral side.

On cutting one of these flowers in two, according to its plane of symmetry, and examining with a strong lens the sections thus obtained, it will be found that the interior is full of the small larvae of a Dipteron, which has hitherto not been determined, and of which as many as 12 to 20 grubs may be seen in a single flower.

In the vesicular portion the tissues of the hood are hypertrophied and the thickness of the cut surface is much greater than in a normal flower. The same change takes place in the tissues of the tube of the stamens which has the appearance of a transparent, thick and rigid column.

It is to be noted that in spite of the presence of numerous parasitic larvae, no part of the flower appears to be injured. The larvae live on the surrounding nectar, the hypertrophy of the nectaries having the effect of increasing the flow. All the deformed flowers remain sterile although their reproductive organs are uninjured. When therefore, as in 1921, they occur in large numbers, the seed production is greatly reduced.

130 - ***Paria canella*. The Strawberry Rootworm in California.** - - URBANUS, T. D., in *Monthly Bulletin of the Department of Agriculture, State of California*, Vol. X, No. 8, pp. 311-313, figs. 3. Sacramento, California, 1921.

*Paria canella* has frequently been referred to as a pest of strawberries and *Rubus* spp. in the eastern parts of the United States. The first mention of this pest was made in 1880, and it has since been reported as a strawberry pest of secondary importance in the States extending from the Rocky Mountains to the Atlantic coast. It came to the attention of Californian growers three or four years ago when its destructive work on the foliage was first noticed. The insect had without doubt been present in smaller numbers for several years previously as it was found to be quite widely distributed. It is found over several widely separated areas in the Sacramento, San Joaquin and Santa Clara valleys. Probably about 300 acres are at the present time abundantly infested and on some of these fields, the strawberries have been practically destroyed.

The adults hibernate in the fields where they may be found active on the warmer winter days. They feed on the leaves in early spring and may be seen in large numbers in early March, when a dozen or more may frequently be found on a single plant. Eggs are deposited on the plants and in soil crevices. The first eggs are laid in the latter part of March

and this continues until May. The maximum is reached in mid-April. The larvae appear in June and soon work their way to the finer roots of the plant. A few of the adults continue throughout the summer, constantly attacking the newly forming leaves. The larvae are fully developed and pupate in July; the new generation appears in early August. These feed ravenously and riddle the leaves. Under Californian conditions, the most severe visible injury results from this attack on the leaves in the autumn and early spring, but the plants suffer even more in mid-summer when the larvae attack the roots and cause the plants to wilt. Punctures made on the leaf stems result in the drying of many leaves and punctures on the fruit give rise to irregular formation and frequently encourage premature decomposition and decay.

A short description is given by the author with reference to the remarkable fecundity of this beetle, and its ravenous attack shows that it is of more than secondary importance to the Californian growers.

Fields infested should be sprayed with arsenate of lead (3 lb. to 100 gall. water), or dusted with Paris green (1 lb. to 6 lb. flour). This treatment should be given as soon as the newly-emerged beetles have appeared, usually about the latter part of August.

Burning the fields is of some value in destroying hibernating quarters for adults, but they escape destruction from the flames by taking refuge under clods and in soil crevices.

Where beetles are found in the spring, fields may be treated with one of the above-mentioned insecticides after the spring rains and before the maximum flowering period.

Poison-bran mash prepared according to the regular formula as used for grasshoppers, has been used with considerable success after the berries began to develop when it is too late to use the insecticides. It has been reported that beetles were found to feed freely upon the poison bait.

131 - On the Presence of the Coccid, *Icerya purchasi* in the Neighbourhood of Paris. — VAYSSIÈRE, P., in *Bulletin de la Société entomologique de France*, No. 15, pp. 215-216. Paris 1921.

A little distribution centre of *Icerya purchasi* has been discovered at Suresnes (Department of the Seine). This appears to be the first time that this scale-insect has been recorded from so high a latitude as that of Paris. The parasite was introduced into the district on young plants of *Acacia* sent from Cannes, and has succeeded in thriving at Suresnes since February 1921. The immediate and thorough destruction of this small centre of infection has been advised.

132 - *Icerya purchasi* in Hérault. — LICHTENSTEIN, J. I., in *Bulletin de la Société entomologique de France*, No. 16, pp. 239-241. Paris 1921.

The coccid, *Icerya purchasi*, already recorded as occurring in France in the Alpes-Maritimes (1) and in the district of Paris (2), has also been

(1) See R. July 1913, No. 891. (Ed.)

(2) See No. 131 of this Review. (Ed.)

discovered in large numbers in a garden at Montpellier (Hérault). Specimens of the insect collected in the district are preserved at the Montpellier School of Agriculture. PICARD and GRASSÉ also found this insect in March 1921 on an acacia in a nursery-garden at Montpellier, but this information has not been published.

In the garden where the author observed *I. purchasi*, the insect was present in enormous numbers and had caused the death of acacias and several specimens of *Glycine* (*Wistaria*), *Sophora japonica* and *Robinia*. The author even found a single specimen on a foreign conifer. The coccid has lived for about two years on these trees and is therefore well able to withstand the winter cold. The author does not think however that it has spread much since its introduction. The place where he found it had a southern exposure and was sheltered from the wind. These conditions have enabled it to develop greatly within a relatively small area, and the author saw none of these coccids on trees growing outside a radius of 20 metres. It should also be noted, that some maples and plane-trees which were literally covered with *Ceroplastes* were quite free from *Icerya*.

The spread of *Icerya* to Hérault must be due to the transport of infected trees; thus its presence is explained in several well-defined spots where it has multiplied intensely, but it only finds its way slowly to other places in the neighbourhood. Although the natural spread of the parasite seems to have been very limited and circumscribed in the cases mentioned, the insect once introduced to a new place rapidly increases, as the author has recently had occasion to observe.

133 - *Agrilus foveicollis*, Coleopteron Injurious to Roses in Bulgaria. —

MOKRZECKI, S. A., in *Bulletin of Entomological Research*, Vol XII, Pt 3, pp. 353-354 + 1 fig London, Nov 1921

In May and June 1921, the author made investigations as to the cause of the serious losses that had occurred among the rose trees (especially *Rosa damascena*) which are extensively grown in Bulgaria for making attar of roses. It has been concluded that the cause of the decline in rose culture is inadequate plant nutrition, owing to an insufficient amount of humus and nitrogen in the soil, aggravated by the neglect of manuring by the growers.

But the immediate cause of death of thousands of rose bushes has proved to be certain galls that are to be found on the stems, reaching 2-3 cm. in length and sometimes as thick as the normal stem. Several galls have been found on a single stem.

When a gall is cut open, dark-coloured burrows may be seen circling the stem just under the bark, the number varying from three to fourteen. Up to the present however no insects have ever been found in these galls and previous investigators attributed them to the coleopteron *Agrilus viridis* L. Injuries of this kind have also been recorded on roses in Italy and France and HOUARD considers them due to the activity of some microlepidopteron.

The author's investigations have however led him to conclude that the galls are caused by the larvae of *Agrilis foveicollis* Mars, a species described in Siberia and never previously recorded for any locality in Europe.

The adult beetles appear in mid May and live on the leaves of roses, nibbling their margins. The female lays her eggs (up to 30) each separately under the bark of one-year-old shoots. The eggs hatch after 5-7 days and during the first 2-3 days of its life, the larva may make as many as three annular burrows round the shoot and under the bark, filled with black excrement. No swelling however is formed during the first summer; the second year, this is noticeable and increases gradually while the shoot begins to dry up. In the third year, the whole stem slowly dries up. The life of the larva lasts apparently about one year, and hence the reason that larvae are not to be found in the galls which are already well formed.

134 - *Laspeyresia molesta*, a Microlepidopteron Injurious to the Peach and Other Fruit Trees reported in Liguria, Italy (1). — PAOLI, G., in *L'Agricoltura Coloniale*, Year XV, No. 12, pp. 572-576, pl. 1. Florence, December 1, 1921.

It has recently been observed that the Tortrycid, *Laspeyresia molesta* Busck, already reported as occurring in Japan, Australia and the United States, is also to be found in Italy, and is even of common occurrence in Liguria.

The caterpillar of this Microlepidopteron lives at the top of the branches of the peach-tree, where it excavates a gallery, thus destroying the terminal bud and causing the branch itself to wither for a distance of 5 to 6 cm. The parasite chiefly attacks trees still in the nursery, or the most vigorous individuals that have been planted out.

The peach-tree is the favourite plant of *L. molesta*, but in Liguria, the insect also attacks young nursery specimens of almond and apricot and is at present but rarely found on *Prunus persica*.

Toward the end of the autumn of 1920, the author discovered in the branches of a peach-tree near Savona, a caterpillar having apparently the characters of *L. molesta*, but it was not until 1921 that he obtained the adult insect and was able to identify it as belonging to the species in question. He found it to be wide-spread and very common from Ventimiglia to Sestri Levante. During a short excursion to Mentone, when the season was already far advanced, the author observed the tops of many of the peach-trees to be injured in such a manner as to justify the belief that this Microlepidopteron also exists in France.

He has not been able to discover in what manner or at what date the insect was introduced into Italy. American varieties of peach-trees are to be seen everywhere in Liguria, but there is no proof of their direct importation from the United States. They have been acquired through the agency of well-known merchants and nursery-gardeners; thus the

(1) See *R. Mar.* 1917 No. 300; *R.* April 1921, No. 443 (*Id.*)

parasite must occur in a number of other districts in Italy, unless it is to be believed that the whole of one infected consignment was sold in different parts of Liguria.

According to the investigations made, it would appear that the withering of the tips of the branches has only been noticed by the Ligurian agriculturists during the last 6 or 7 years. It is not however likely that the *Microlepidopteron* was introduced so recently, for all insects escape observation at first; further nearly two hundred kilometres of the Riviera, from Ventimiglia to Sestri Ponente have been invaded by *L. molesta*.

The author describes the different stages of the insect's development and the injury it occasions.

No really efficacious means of controlling this Tortrycid are at present known

GENERAL INFORMATION.

- 135 - Agriculture in the State of São Paulo, Brazil, According to the President's Message to the Legislative Congress (Session of July 14, 1921). — *Industria e Comércio*, Year VI, No 55, 30 pp. Rio de Janeiro, July 31, 1921.

DEVELOPMENT  
OF  
AGRICULTURE  
IN  
DIFFERENT  
COUNTRIES

The greater part of the Message of the President of the State of São Paulo, Dr. Washington Luis PEREIRA DE SOUZA, is concerned with the economic and financial condition of the country during the difficult period beginning with the termination of the European War. He describes the measures taken by the Government to alleviate the serious crisis which was due : to the sudden fall in price of all articles of food, the decreased consumption of the countries that had previously been the chief importers of Brazilian products, the resumption of home production in those countries, the precarious condition of the Brazilian market owing to the sudden influx of North American goods, in quantities that far exceeded the demand, thus causing the export of gold coinage and the rise of the exchange which was already very high owing to the above mentioned causes, etc.

In São Paulo the crisis first affected stock-breeding and the industries of which it is the basis : cold-storage plants, tanneries, boot-factories, etc., but it soon extended to cereal production and the cereal trade, cotton-growing and the cotton industry, etc. The coffee crisis was not occasioned, as in the other cases, by an excess demand over supply, but by the fact, that there was a severe frost in the State on June 25, 1918, which destroyed the year's crop and reduced by 70 % the normal yield for the two following seasons.

The President has carefully studied the best means of organising Credit Institutes in order to tide over the present difficulties and prevent their occurrence in the future. He deals chiefly with the necessity for founding a Central Bank of Credit and Discount.

The taxes of the year 1920 brought in a total of 175 678 985 *milreis*, of which 27 266 750 were furnished by export dues, 13 120 by the sale of public lands and 380 246 by the sale of holdings to groups of colonists.

IMMIGRATION AND PROTECTION OF THE AGRICULTURAL WORKER. — Immigration, which was suddenly arrested by the outbreak of hostilities in Europe, has now resumed its normal proportions. In 1920, 44 553 immigrants entered the State of São Paulo; of these, 32 484 landed at Santos.

The President considers that the present form of settler's contract cannot be improved upon, as it allows the settler working at the "fazenda" to save money and thus acquire the position of small-holder or merchant.

The "Patronato agrícola" protects the rights and interests of the rural workers, and acts as arbitrator in the case of difficulties arising between employers and their men; it gives advice to rural workers and land-owners, settles strikes etc.

AGRICULTURAL INSTRUCTION. — This is given at the following Institutions: a) The "Escola agrícola Luiz de Queiroz", which confers an agricultural diploma and had 103 pupils and 10 students attending lectures, in 1920; b) The "Instituto de Veterinária" opened in April 1920, with 17 students.

The State also provides for general instruction (both secondary and University teaching), as well as for the education of persons entering professions or trades.

GOVERNMENT MEASURES FOR THE ENCOURAGEMENT OF AGRICULTURE. — *Instituto agrônomo do Estado*. — The director of this Institute answers written or verbal questions regarding agriculture; in his chemico-bacteriological laboratory are carried out analyses of soils, fertilisers, insecticides, agricultural produce (which is also examined when adulteration is suspected), experiments in agricultural microbiology and plant biology, etc., and its services are also at the disposal of private individuals. The Institute has an experimental and demonstration coffee plantation, where the theoretical and practical study of the systematic cultivation of the coffee plant is carried out. There is also an experiment field for polyculture, where the improvement of farm-crops, the best methods of growing crops on a large scale, the best varieties of plants grown, the acclimatisation and selection of plants, the most favourable dates for sowing, etc. are thoroughly studied. In 1920 the Institute distributed 174 450 plants, including fruit-trees, ornamental plants, sugar-canes, coffee trees (cuttings, grafted stocks, rooted cuttings).

The *Forestry Service* supplies trees gratuitously to public Institutions, and at a low price to private persons. In 1920, it distributed 1 577 826 trees; of these 1 517 865 were forest-trees, and 59 961 fruit-trees.

The *Meteorological service* possesses 111 Stations in the State of São Paulo.

*Propaganda of "Agricultural Protection"*. — The "Directoria de agricultura" not only brings to the notice of agriculturists the methods that experience has shown to be the best for obtaining good crops, but

also directly assists by its advice and efforts in lessening the injury caused to cultivated plants by pests and parasites. Chief among these is the Pink Cotton Boll-Weevil "*lagarta rosada*" (*Platyedra* [*Pectinophora*] *gossypiella*), an insect remarkable for its diffusion and the great injury it inflicts on the cotton crop.

*Novius cardinalis* has been introduced and become acclimatised, and its power of controlling *Icerya purchasi* ("pulzão branco") has already been observed. Studies and experiments are being carried out with a view to the extermination of the "formiga sauva" (ternrite).

The "Directoria de Agricultura" distributed in 1920 36 614 kg. of Paris green, 17 020 kg. of white arsenic, 9 216 kg. of flowers of sulphur, 2 279 kg. of copper sulphate, and 53 boxes of carbon disulphide.

The Service for the Inspection and Sorting of Cotton Seeds continues the inspection of the ginning establishments, in order that no seed infected with bollworm may be planted: 327 of these establishments were inspected. The trucks in which the sorted seeds are transported are also disinfected.

*Sale of Agricultural Implements at Cost Price.* — 29 007 picks and spades, 10 301 pickaxes were sold as well as pitch-forks scythes, drills, PLANET harrows, etc.

*Seed Distribution.* — In 1920, 8 709 kg. of seed were distributed to 2 436 persons.

*Publications Service.* — The "Secretaria de Agricultura" of the State of São Paulo has 3 official publications: *Boletim de Agricultura*, *Boletim de Industria e Commercio*, *Boletim de Importação e Exportação do Porto de Santos*. The number of publications (including periodicals) distributed in São Paulo amounted to 220 000.

*Coffee Propaganda.* — This work is entrusted to different companies; the contract for Japan being given to the "Companhia Café Paulista" of Tokyo, and that for the United States to the "Sociedade Promotora".

*Measures for the Encouragement of the Stock-Breeding Industry.* — In 1920, the "Directoria de Industria Pastoral" distributed over 200 000 doses of vaccines against infectious cattle-diseases. This office was wound up in 1920, and since then the vaccines have been sold by the Ministry of Agriculture to the breeders entered on its registers.

The Police Veterinary Service was instituted by Decree No. 3141 of January 13, 1920. This Service has succeeded in confining rinderpest to a very limited area, and in rapidly suppressing it; the disease having been rife throughout the state of São Paulo at the beginning of 1921. The method employed consisted in the marking out of the infected area and the destruction within this area of all animals likely to contract the disease; 1454 cattle were slaughtered and their owners indemnified.

Good results have been obtained at many Stud Stations. At the "Posto de Seleção do Gado Nacional" the work of improving the Caracú cattle has been continued (1) and at the "Haras paulista" the native horse

(1) See R. 1911, No. 1825; R. 1912, No. 1438; R. 1916, Nos. 1093 and 1195; R. 1917, No. 1044. (Ed.)

is being improved (1). The "Fazenda de Criação" of Barnery is chiefly engaged in pig-breeding, but pure Schwytz cattle are also bred there, the animals doing exceedingly well (2). The "Fazenda Sant'Anna" has become the centre of Dutch cattle breeding. The pure Red Poll race is also bred at the "Fazenda de Criação do Amparo"; the pastures and breeding methods in Brazil suit this breed of cattle. At the "Fazenda de Criação at Itapetininga, Hereford and Durham cattle are reared and also sheep. The "Fazenda Campininha" is set apart for the breeding of the native "gado mocho" cattle and to its improvement by selection and proper feeding. It is also engaged in the intensive and extensive cultivation of forage plants either native, or capable of acclimatisation. The results already obtained have been encouraging. The "Posto zootechnico" of Botucatú and São Paulo respectively are two popular Stud Stations; the latter is also a vaccination Station.

A cattle show was held on April 12. The first class animals (excellent), fetched 20 *milreis* per *arroba* (1 *arroba* = 33 lb. = 15 kg.); the second class (good), 18 *milreis*; the third class (fair), 16 *milreis* and the fourth class (disqualified), 15 *milreis* respectively per *arroba*.

AGRICULTURAL PRODUCTION. — In 1919-1920, the frequent and abundant rainfall was very beneficial to cereals, especially to rice. On the other hand the cotton crops were very small (only half the normal crop being produced on account of a reduction of the area under cotton due to the fall in prices and the attacks of parasites). Table I gives the chief crops obtained during the year in question and their value in *milreis* (1 paper *milreis* = about 1 s. 6 d.).

TABLE I. — *Agricultural Production in the State of São Paulo in 1919-1920.*

Products		Amount	Value in <i>milreis</i>
Coffee . . . . .		—	278 908 640
Unginned cotton . . . . .	qx	688 245	43 588 840
Sugar . . . . .	sacks	528 821	33 971 161
Brandy and alcohol . . . . .	hl.	953 880	49 406 877
Tobacco . . . . .	qx	32 326	68 807
Paddy . . . . .	sacks	4 686 015	82 005 262
French beans . . . . .	"	2 859 377	40 031 278
Maize . . . . .	"	15 963 900	183 854 850

The value of the total agricultural production of the preceding year had been 955 606 300 *milreis*.

(1) See R. June 1921, No. 469. (Ed.)

(2) See R. Oct. 1921, No. 1031. (Ed.)

THE FROZEN MEAT INDUSTRY (1). — This industry is at present carried on at the Refrigerating Stations belonging respectively to the "Companhia Frigorifica e Pastoril" (at Barretos), the "Continental Products" (Osasco), the "Companhia Frigorifica de Santos" (Santos), and Messrs Armour (near São Paulo).

The capital employed in these establishments is 36 million of *milreis*. The three first used in 1919 :

238 664	cattle of a dead weight of	53 532 911	kg.
65 182	pigs	5 025 194	"
2 253	sheep	30 908	"

their output being : 34 748 747 kg. of frozen meat ; 4 609 279 kg. of chilled meat ; 13 016 400 kg. of fresh meat ; 2 458 679 kg. of tinned meat.

The value of this output was about 70 million *milreis*, as against 56 million in 1918.

The exportation of meat from the port of Santos began in 1914 with a first consignment of 1415 kg. and has progressed as follows :

Years	Frozen meat		Tinned meat	
	Weight in kg.	Value in <i>milreis</i>	Weight in kg.	Value in <i>milreis</i>
1915	7 946 745	5 739 112	93 325	132 700
1916	18 688 846	15 716 962	362 173	612 719
1917	29 134 755	26 388 613	1 097 129	1 738 224
1918	32 654 838	32 754 404	2 791 181	5 222 855
1919	32 033 736	35 606 480	2 877 745	6 683 553
1920	32 710 000	36 532 000	570 172	1 425 093

The chief markets for Brazilian frozen meat are : Italy, Great Britain, Egypt and France, the tinned meat mostly goes to Belgium and Great Britain, and the sale of this commodity has been much reduced by the loss in 1920 of the North American market.

INDUSTRY AND COMMERCE. — The value of the output of the manufacturing industries of the State of São Paulo continues to increase ; from 274 millions of *milreis* (in round numbers) in 1915, it rose in 1919 to nearly 713 millions.

In 1920, the value of the exports was 53 250 000 *pounds sterling*, or 860 million paper *milreis*, with a decrease of 227 million paper *milreis* as compared with the preceding year. This drop is to be attributed chiefly

(1) R. July 1921, No. 767. — Regarding the exportation of frozen and tinned meat from Brazil to Italy see : Dr. DROGECIO DE CAMPOS, A importação de carnes congeladas na Italia, in *Boletim do Ministerio das Relações Exteriores, Republica dos Estados Unidos do Brasil*, No. 9, pp. 49-2. Rio de Janeiro, 1920. (Ed.)

to coffee of which 9 426 335 sacks (of 60 kg.) of the value of 946 576 million of *milreis* were exported in 1919 as against 8 480 887 sacks of the value of 671 363 million *milreis* in 1920.

In 1920, the export figures for cotton were the highest hitherto registered being 11 260 tons of the value of 38 689 000 *milreis*, or about double the amount exported in 1919; 83 331 tons of rice of the value of 59 893 000 *milreis* were exported as against 8 846 tons in 1919.

The sea trade of the Port of Santos is now as great as before the War.

**SANITARY SERVICE.** — The Public Health Services continue to insure the interrupted improvement of the hygienic conditions of the country. They have at their disposal: vaccinogenic, bacteriological and Pasteur institutes, as well as factories where State quinine is made; services for the Inspection of food sold to the public (with Laboratories for the analysis of chemical products and foods); a corps of Sanitary Engineers; a Service for the Inspection of Chemists' shops; an Inspector of general prophylaxis; a Central Institute for Disinfection; a Hospital for Infectious Diseases, etc.

These Services also provide for the hygienic protection of infants.

#### RURAL HYGIENE

136 — **The Part Played by the Rabbit and Other Domestic Animals in Protecting Man from Mosquitoes.** — LEGENDRE, J., in *La Nature*, No. 2487. Paris, December 3, 1921.

There have been previous references to the rôle of animals in protecting man against the bites of the mosquitoes that convey malaria. Domestic animals living in the neighbourhood of human beings are attacked by *Anopheles maculipennis* in preference to the latter (1). The author, basing his opinion upon the observations made in collaboration with OLIVEAU, states that the rabbit is very useful in this connection. In many districts of France, the rabbit enclosures have been found to be infested with *Anopheles* when the stables and houses near were completely free even in summer. The young rabbits are bitten in the hairless parts of their bodies, viz., the ears and muzzle.

### CROPS AND CULTIVATION

#### AGRICULTURAL METEOROLOGY

137 — **Effect of Lake Michigan (United States) upon Rainfall during the Crop-Growing Season.** — ESHLEMAN, C. H., in *Monthly Weather Review*, Vol. 49, No. 9, pp. 500-502, figs. 2. Washington, September 1921.

Severe drought conditions prevailed during the early and middle crop-growing months of 1921 at Ludington (Michigan), and the storms seemed in some degree to avoid the shores of Lake Michigan although heavy rain fell in the neighbourhood.

These facts led the author to undertake a series of investigations with a view to determining whether the lake diminished the total rainfall.

The data obtained showed that for the three months May, June and July, there is an area of maximum rainfall in the interior of extreme Southern Michigan. In August and September this area is absent.

(1) See *R. Jan.* 1920, No. 1. (Ed.)

The rainfall is greater on the eastern than on the western shore, whereas an area of maximum distribution is found in the interior of Wisconsin (on the west of the lake).

The lake thus seems to cause a certain decrease in the rainfall which must be attributed to the wind blowing with greater force in the afternoons, during May, June and August and thus producing a lateral movement preventing the vapour-laden air from rising and its moisture from condensing in the form of heavy rain.

138 - **The Fertilising Value of Rain and Snow (1): Researches in Canada.** — SHUTT, F. T. (Chemist of the Dominion of Canada), Chemist's Report, in *Rapport des Fermes Expérimentales du Dominion. Fiscal Year Ending March 31, 1920*, pp. 58-59. Ottawa 1921.

A study begun in 1907 with a view to determining the sum of available nitrogen annually supplied per hectare by rainwater and snow; the water was collected and the analyses were made at the Central Farm in Ottawa. All the rainfall and the snow that have fallen during a year are separately measured and analysed. This latter is an important point for it was found at the beginning of the work, that the analysis of samples taken every month and preserved by means of an antiseptic does not give accurate results.

The laboratory work was limited to determining the free ammonia, albuminoid ammonia, and nitrous and nitric nitrogen. These three forms are those which make up the nitrogenous compounds present in atmospheric precipitations which are able to supply the crops with fertilising substances.

During the year ending February 29, 1920, 79 samples of rain and 24 of snow were analysed. The total precipitation registered for the year March 1, 1919—February 29, 1920 was 844 mm. of which 594 mm. were rain and 2502 mm. were snow (10 mm. of snow equals 1 mm. of rain). The total amount of nitrogen supplied by these precipitations was 7 971 kg. per hectare.

This enquiry brought to light many facts of scientific interest, but it will suffice in this short account to give such data only as are of importance from the agricultural standpoint. These are set out in the following Table together with similar data for the 2 preceding years for purposes of comparison, and the mean for the first decade of this experiment.

The rain and snow fall for the year are about normal. The mean for the 29 preceding years is 855.5 mm., but the amount of nitrogen supplied slightly exceeds the average given during the first 10 years of these researches. The latter show that the atmospheric precipitations in the neighbourhood of Ottawa supplied about 7.28 kg of available nitrogen per hectare. Of this amount 85 %, or about 6.6 kg., are supplied by the rain. The value of the nitrogen derived from the rain and the snow may be estimated, at a moderate computation, as 22.40 fr. per hectare (at par).

(1) See R. 1912, Nos. 39 and 620; 1914, Nos. 202 and 491; 1915, No. 677; 1916, No. 7; 1918, No. 956. (Ed.)

*Rainfall and Snow (in mm.) and Amount of Nitrogen supplied (in kg. per ha.)*

	Total amount m. m.	Nitrogen supplied

Year ending February 29 1920. . . . .	844.04	6.618	1.353	7.971
<i>Average of the 10 years ending on February 28, 1917. . . . .</i>	<b>842.52</b>	<b>6.142</b>	<b>1.223</b>	<b>7.375</b>

139 - **Influence of Atmospheric Factors upon the Composition of Wheat.** — See No. 160 of this Review.

140 - **Hard-Pan in the Apulian Soils and Its Origin.** — DE DOMINICIS, A. (Laboratorio di Chimica agraria, della R. Scuola Sup. di Agricoltura, Portici), in *Annali della Regia Scuola Superiore di Agricoltura in Portici*, Second Series, Vol. XVI, p. 18. Portici, 1920.

In a preceding paper the author (1) gave an account of the results of his researches on the hard-pan (« crosta pugliese ») of the soils of Apulia, especially in the district of Bari, where in many places the pan firmly adheres to the calcareous tufa that forms a rocky massive subsoil. The special conditions prevailing in the country round Bari are however not generally found in the rest of Apulia, for here the hard-pan rests for the most part on a friable, more or less finely divided calcareous soil into which roots can easily penetrate. This being the case the author decided to extend his researches to the other parts of Apulia and see how far the results obtained agreed with or differed from those of his previous investigations.

He employed the same methods as before, examining on the spot the position, conditions of formation, composition and properties of the hard-pan, its probable origin and the consequences of its possible removal.

These new researches bring out the general significance of the data previously obtained and also prove that hard-pan is not a phenomenon confined to rocky, massive sub-soils. They show that the formation of Apulian hard-pan in particular, and of all superficial calcareous pans in general, always depends upon the same set of conditions: a) the opportunity for their formation at the point of contact of the soil and the subsoil — b) a dry climate and a subsoil consisting of a rocky mass rich in calcium carbonate and with a very active capillary system — c) calcium carbonate dissolved in the capillary water, and the presence in the circulating water of sufficient colloidal substances in the form of reversible hydrogels and hydrosols — d) the co-existence of all these conditions which entails: 1) similar properties viz. a) a permeability limited to the first few moments of the action of the water and only to be detected by the application of certain methods — b) a capillarity not extending beyond the thin coating on the

(1) See R. March 1920, No. 293. (Ed.)

surface of the crust; 2) similar chemical composition, the chief constituents being: a) calcium carbonate derived from the subsoil; b) sandy and clayey matter from the soil.

Hard-pan is thus always formed in the same way and is due to the coagulations that take place when the colloidal substances found as hydrosols in the circulating water come into contact with the bivalent electrolyte, calcium carbonate, dissolved in the capillary water. The content and proportions of the crust depend upon the capacity of calcium carbonate absorption possessed by the resulting mass. These principles have been confirmed by new facts revealed by the present researches which have also shown how Apulian agriculture can be assisted by the improvement of both compact calcareous subsoils and non-massive calcareous subsoils. The first are more difficult to deal with than the second. Compact ground is however best broken up by the use of explosives, while friable soils only need superficial clearing.

141 - Researches made in Japan on the Gases Formed in Rice Fields during the Decomposition of *Astragalus sinicus* used as a Green Manure. — ONODERA, S., in *Berichte des Ohara Instituts für Landwirtschaftliche Forschungen in Kuraschiki, Province of Okayama, Japan* Vol I, Part 5, pp 557-558, figs. 12. Kuraschiki, 1920.

*Astragalus sinicus* L. is the plant chiefly used for green-manuring in Japan. Although it forms 71 % of the total of the Japanese green manures, it sometimes injures the rice crops, either on account of the nature of the soil or on the amount of the dressing applied. The author has already had occasion to try and discover the cause of its ill effects; it would appear that these are to a certain extent due to the salts of the organic acids liberated during the decomposition of *Astragalus sinicus*. He subsequently found that the decay of this plant in the rice-fields gave rise to the formation of much larger quantities of gas than would be supposed. Much work has been done on the nature of soil gases; and the researches of LEWY, BOUSSINGAULT, RUSSELL and APPLEYARD may be mentioned in this connection.

	Carbon dioxide	Oxygen	Nitrogen	
Cultivated soil . . . .	$0.25 \pm 0.1\%$	$20.6 \pm 0.2\%$	$79.2 \pm 0.2\%$	{ RUSSELL and APPLEYARD, 1919
Winter meadow . . . .	1.57	18.02	80.04	
Atmospheric air . . . .	0.03	20.97	79.90	
Cultivated soil . . . .	0.90	19.60	79.50	{ LEWY and BOUS- SINGAULT, 1853

According to RAMANN, the air of the soil contains 0.3 % of carbon dioxide, which is more than is present in atmospheric air, but soil air is free from methane and hydrogen. Researches on the gases of rice-fields have been made in India, though no author has considered the part played by

*Astragalus sinicus* in gas production. The author collected all the gases liberated during the summer of 1918 by the soil in a pot manured with *Astragalus sinicus* and then turned over. In 1919, he collected the gases from a rice-field fertilised with the same green manure. They included the gases from the slightly stirred superficial layer, the gas spontaneously liberated and the gases from the sub-soil. The soils studied were sandy-clays and clays.

The author's conclusions showed that *Ast. sinicus*, when used as a green manure for rice fields, set free large quantities of gas consisting essentially of methane, carbon dioxide, nitrogen and a small amount of hydrogen, the latter disappearing at the end of the decomposition process. Sometimes a little oxygen was found, which probably did not come from the decomposition of *Astragalus* but was a product of the carbon assimilation of the algae. If *Ast. sinicus* is left to decay in a rice-field, the gases of the subsoil contain more carbon dioxide than methane while most of the nitrogen is to be found in the upper layer. *Ast. sinicus* decomposes more rapidly in sandy soil than in clayey-sands and more quickly in the latter than in clays, hence the liberation of gases comes to an end sooner in sandy soil than in others.

It should be mentioned, that no liberation of gas from the control plots was observed and even had they formed a small quantity it would have consisted chiefly of oxygen, nitrogen and sometimes of small amounts of carbon dioxide; further, given its composition, this gas must be attributed to the carbon assimilation of the algae. It should be noted that the application of a little toluene soon stopped the liberation of gas.

142 - **The Inversion of Saccharose by the Mineral Acidity of the Soil.** — OSUGI, S., in *Bericht des Ohara Instituts für landwirtschaftliche Forschungen in Kuraschiki, Province of Okayama, Japar*, Vol. I, Part 5, pp. 579-597. Kuraschiki, 1920.

The power of inverting saccharose, a property possessed to a high degree by soils containing much mineral acidity, had already been demonstrated first by the author alone, and then in collaboration with RICE (1), as well as by SHARP and HOAGLAND. As the question had not been explained thoroughly, the author made further experiments using 11 samples of soil. He treated 5 gm. with 100 cc. of 5 % sugar solutions for 1 hour at 85° C, and then made the following determinations for the filtrate: the inverting power of the soil — the effect of the acidity of the soil extract — the effect of the temperature — the effect of various chemical agents — the effect of the different proportions of the degree of the acidity of the soil and its inverting property — the rapidity constant of the inversion reaction caused by acid soils.

The author then sought to discover the substances, whether extracts or insoluble (fine soil particles, silicic acid gel, or silicate of alumina), that might possibly cause the inversion of sugar.

His researches proved that a soil containing no mineral acidity un-

(1) See R. Feb. 1919, No. 158. (Ed.)

doubtedly has the power of inverting saccharose to a measurable extent, 1 to 9 gm. of invert sugar being obtained per 100 of saccharose. This property of inversion is to be attributed chiefly to the soil particles and is strictly connected with the degree of acidity of the extract obtained by treatment with a saline solution of potassium chloride.

The inversion produced by acid soil is a mono-molecular reaction similar to that effected by acids; on the other hand, aqueous extracts of acid soils are found to contain a little aluminium sulphate or chloride with acid reaction, but producing very little effect on the saccharose, whereas the gel of silicic acid can invert saccharose, but is not found in determinable quantities in acid soil. There is, however, an acid silicate (obtained by the precipitation with an aluminium salt, of an alkaline salt in an acid medium) that inverts saccharose and is the substance to which the great inversion power of acid soil is chiefly due.

The concentration of the hydrogen ions of aqueous acid soil extracts is not sufficient to cause inversion on the part of the soil, unless it is to be assumed that these ions are more concentrated in the film surrounding the soil particles than is any other part of the soil solution.

143 - **The Prevention of Dust Storms in Canada.** — MUNRO, W. A (Régisseur de la Ferme Expérimentale, Rostern Sask.), in *Rapport des Fermes Expérimentales du Dominion. Fiscal Year Ending March 31, 1920*, pp 171-172. Ottawa, 1921.

METHODS  
OF  
CULTIVATION

As much damage had been done in 1919 throughout the greater part of Saskatchewan by the removal of soil by winds, the author devoted his attention to a careful study of the question. From his observations and the results of his experiments, he reached the following conclusions:

1) Dust storms can be prevented to some extent by liberally manuring every 4 or 6 years.

2) Sowing grass-seed once in 6 years and allowing the grass to grow for at least 2 years is useful.

3) A clump of trees protects the ground on the leeward side for a distance of 15 m. for every 30 cm. of the trees' height.

4) No garden can succeed, unless it is protected by good wind-breaks in the shape of hedges.

144 - **The World's Nitrogen Products.** — *Journal of the Society of Chemical Industry*, Vol. XL, No. 15, pp. 285-287. London, August 15, 1921.

MANURES  
AND  
MANURING

The following data have been taken from the Statistical supplement to the Final Report of the Nitrogen Products Committee of the Ministry of Munitions. They show the present sources of the supply of these products which are most essential to agriculture and bring out the fact that the nitrogen fixation industry will in future be the chief source of nitrogen for the whole world, as can be seen from Table II.

The demand for fixed nitrogen is growing at a greater rate than the output capacity. As Table I shows, the potential output of the cyanamide plants is greater than that of the synthetic ammonia plants.

TABLE I. — *National Internal Sources of Fixed Nitrogen in Different Countries.*

Country	Population	Metric tons of nitrogen

145 - **The Condition of the Nitrogenous and Phosphatic Fertiliser Industries in Germany.** — UNGEWITTER, in *Chemiker-Zeitung*, Year XLV, No. 147, p. 191. Cöthen, December 8, 1921 (1).

The pre-War consumption of nitrogen in Germany amounted to about 240 000 tons, of which 40 000 were used in industry, and 200 000 in agriculture, not including the nitrogen supplied to the land in the forms of dung and green manure. This nitrogen was obtained : a) by the importation of the nitrate of sodium (in 1913, some 7 500 000 tons were imported, equivalent to 116 250 tons of nitrogen) ; b) by the importation of nitrate of lime (in 1913, 20 000 tons representing 2 400 tons of nitrogen were imported) ; c) by the home production of sulphate of ammonia (in 1913-1914, 500 000 tons corresponding to 110 000 tons of nitrogen were made) ; d) by the home production of calcium cyanamide (amounting in 1913-1914, to 50 000 tons representing 10 000 tons of nitrogen). During the War, these importations ceased. They were however replaced by the manufacture of ammonia on a large scale by the HABER-BOSCH high-pressure method, and of calcium cyanamide according to the FRANK-CARO process, but the ever-increasing need of munitions for the army encroached upon the supply of nitrogenous fertilisers for agriculture. After the revolution the nitrogen production fell to about  $\frac{1}{3}$  of the maximum output during the War, but it has gradually improved, so that according to the data of the Food Ministry, the amount of nitrogen supplied for agricultural use from 1914 to 1920 was as follows (in tons) :

1914	1918	1919	1920
200 000	92 000	115 000	158 000

In 1913 and 1914, 774 000 and 31 000 tons of nitrate of sodium respectively were imported into Germany. The maximum nitrogen output of the HABER-BOSCH process is estimated at 300 000 tons and that of the calcium cyanamide process at 100 000. The maximum production of the coal distilleries and gas factories may be reckoned at 100 000 tons of nitrogen, so the total maximum annual amount at disposal would be 500 000 tons. It must not be forgotten, that the Joint-Stock Nitrogen Co. ('Stickstoff Gesellschaft m. b. H. '), was founded in order to assist in providing nitrogenous fertilisers for agricultural purposes.

The question of supplying the raw materials necessary to the phosphatic fertiliser industry is at present a matter of the greatest difficulty. The last tons of the large pre-War reserve of mineral phosphate were already exhausted in 1916. Since that date until the middle of 1919, all the phosphates at the disposal of the industry were of inferior quality ; some coming from the Lahn deposits, and the rest from other sources. In 1913, 88 superphosphate factories used 900 000 tons of crude phosphate coming almost

(1) See R. Sept. 1921, No. 890 ; R. Nov. 1921, No. 1091. (Ed.)

exclusively from over-seas; during the War 5 factories failed and 28 were obliged to shut down owing to lack of raw material. It was not until the last six months of 1919, that it was again possible to import material of good quality, and then the price was prohibitive, for Government aid was refused in the first instance, although it was then of paramount importance. In 1920, 133 000 tons of mineral phosphate were imported, and from the beginning of 1921 both the Government and the industry have made every effort to restore the importation of raw material to its normal condition; 61 superphosphate factories have thus been able to resume work. The amount absolutely necessary for the present season is 500 000 tons. In 1919-1920, the quantities of phosphatic fertilisers supplied to agriculture compared with the amount furnished in 1913-1914 were as follows (calculated as phosphoric acid).

	1913-1914	1919-1920
Basic slag . . . . .	391 000	118 000

146 - **Manurial Value of Tobacco Waste.** — SHUTT, F. T. (Chimiste du Dominion du Canada), Report of the Minister, in *Rapport des Fermes Expérimentales du Dominion* Fiscal Year ending March 31, 1920, pp. 52. Ottawa 1921.

The waste of the by-products of tobacco factories (dust, ribs, etc.), possesses an appreciable but uncertain value as an insecticide and fertiliser. Potash and nitrogen are the chief nutritive substances it contains. When these residua are bought for use, an analysis giving the percentage of these elements should be obtained, for the poorest types, such as tobacco dust, often contain large quantities of sand. The following analyses show the differences in composition and hence in value of these waste products.

*Analyses of the Residua of Tobacco Factories.*

	Water	Ash	Loss on incineration	Insoluble residue	Phosphoric acid	Potash	Nitrogen
Dust of tobacco No 1 . . . . .	2.29 %	76.30 %	21.41 %	70.57 %	0.12 %	0.65 %	0.59 %
Dust of tobacco No 2 . . . . .	4.25	44.57	51.18	34.75	0.40	1.62	1.39
Dust of tobacco No 3 . . . . .	3.17	63.44	33.39	55.20	0.19	1.07	0.89
Stalks of cigarette tobacco . . . . .	7.87	18.53	73.60	0.55	0.63	4.49	1.04
Stalks of « Burley » . . . . .	7.03	22.56	70.41	0.38	0.92	7.69	2.89
B. E. Stalks . . . . .	7.45	22.57	69.98	0.43	0.52	7.60	1.47

- 147 - **United States Production of Fish Scrap and Meal.** — *The American Fertiliser*, Vol. LV, No. 10, p. 92. Philadelphia, Nov. 5, 1921.

According to the *Report of the Bureau of Fisheries, Department of Commerce*, the estimated production of fish and whale scrap and meal in 1920 was 130 000 tons, a material increase over previous years. Of this amount 16 898 tons are credited to the Pacific Coast States and Alaska. On the West Coast, as a result of the heavy demand for fertiliser material, more than the usual amount of scrap was used for this purpose. In the "menhaden" industry of the Atlantic coast, the value of the Bureau's assistance in encouraging the production of fish meal has been greatly appreciated. At least 5 000 tons of meal were turned out by the producers in 1920 and considerable quantities of unground scrap are stated to have been sold to manufacturers interested in supplying stock feeds. The Bureau of Animal Industry of the Department of Agriculture has continued its hog-feeding tests, using various fish meals, and samples have been supplied to some fifteen State experiment stations with satisfactory results. The experiments in progress include the feeding of meal with high oil content, samples without removal of natural oil with additional oil added and meal made from decomposed fish. If these tests yield satisfactory results, the producers of fish meal should be reasonably assured of markets for their product as the farmers have become acquainted with its merits. The whaling companies have recently expressed an interest in the manufacture of whale meal and have provided material for a feeding test.

Considerable quantities of fish offal and waste fish incident to the New England fisheries remain unutilised, and in some cases its disposal is an item of no little expense to the producer. Lack of a regular supply makes the operation of the larger reduction plants impracticable, and the smaller plants do not appear to be wholly satisfactory for the proper reduction of some of the raw materials in greatest abundance. The Bureau appreciates the need of solving the problems in this field and hopes to be in position to take them up in the near future.

- 148 - **The Sébakh of the "Koms" or "Sébakh koufri", in Egypt.** — MOSSERI, V. M. (Vice President of the Egyptian Institute), in *Bulletin de l'Institut d'Égypte*, Vol. III, pp. 75-92, fig. 1. Cairo 1921.

"Tafla", "marog" and "sébakh" from the "koms", or "sébakh koufri", are nitrogen earths forming the chief natural fertilisers of Egypt. "Sébakh" from the "koms" is the most widely-used, and was employed at an earlier date than either of the others. "Sébakh" means manure and "kom" signifies heap or mound; this fertiliser is also called "sébakh koufri" or simply "koufri". It is a pulverulent substance used for manuring or improving the soil and comes from the rubbish heaps that gradually accumulate near towns or villages when they have repeatedly been destroyed and rebuilt on the same site during the course of centuries. The author had the opportunity of examining over 250 "koms" of

koufri " and gives a few general ideas acquired from his investigations.

The " koufris " consist for the most part of rubbish, and they are poor in fertilising substances, but they differ according to the locality, the mound from which they are taken, or even the stratum of the same mound. The " sébakh " of the " komis " can be applied as a fertiliser or for improving the land, but in either case it nearly always has some perceptible effect upon the soil which may be favourable or unfavourable according to circumstances. It is always well, if not indispensable, to determine the composition of the " sébakh " before applying it. We may consider two ways in which " koufris " are used.

1) In the case of normal alluvial soils, " koufri " is applied as a fertiliser and should chiefly be regarded as a source of nitrogen. Its importance in this respect depends on the nitric nitrogen it contains (under the form of nitrate of sodium) which varies from traces to 35 %.

Ammoniacal nitrogen is only present in such negligible quantities that it can be disregarded without causing serious error in the calculation, and organic nitrogen can be left out of the reckoning as its nitrification is doubtful, and in any case too slow.

2) For all other soils, " koufri " may be looked upon as a source of nitrogen, phosphoric acid or potash. It is however very rarely that these substances are present in the proportions required to make a complete fertiliser, hence it is nearly always necessary to add some other fertiliser, preferably a nitrogenous. The amount of total nitrogen must here be taken into account and also the quantity of organic substances present which by their physical action, may become of considerable importance as affecting the compactness or friability of the soil. As regards the phosphoric acid (which is present to the extent of 1.3 % of phosphoric acid soluble in citrate of ammonium), and the potash (0.096 % to 2.280 %, soluble in 1 % citric acid), only the available amount in the " koufris " has to be determined and reckoned.

It must not be forgotten, that the " koufris " always contain soluble salts (common salt to the amount of 0.57 to 13.40 %). Some of these are injurious, while the others are either innocuous, or beneficial; hence it is necessary to note the nature of these salts and the proportions in which they are present. It is not always possible to know beforehand how much of these salts the " koufri " can contain without rendering it unusable, for this depends upon the nature of the soil to be manured or improved, the drainage conditions, the course of the underground water, etc. If the soil is permeable, well-drained, either naturally or artificially, and the level of the subterranean water is fairly low, the " sébakh " can safely contain rather large quantities of injurious salts. Should the contrary be the case, care must be taken to avoid applying an appreciable amount of these substances to the soil.

The author mentions the uses that can sometimes be made of the salts in the " koufris " and their value for improving more or less alkaline land.

- 149 - **Distribution of Manganese in the Organism of Higher Plants.** — BERTRAND, G., and ROSENBLATT, M., in *Comptes rendus de l'Académie des Sciences*, No. 22, pp. 1118-1120. Paris, November 28, 1921.

After having proved that manganese is of general occurrence in plants (1), the authors endeavoured to ascertain the manner in which this metal is distributed, both in the different organs of plants, especially of the higher plants, and also in the various parts of any specimen gathered at a given growth period.

The results obtained show that a large amount of manganese is present in the organs that are the seat of active metabolism in the reproductive organs, leaves, young shoots and in all the organs containing chlorophyll as well as in seeds.

- 150 - **The Manganese Content of Seeds of Dutch Origin.** — WESTER, D. II., in *Biochemische Zeitungsschrift*, Vol. CXVIII, pp. 158-163. Berlin, 1921.

There is good reason to believe that manganese plays a considerable part in plant metabolism, but though the manganese question, as it may be called, has been the subject of considerable investigation during the last 25 years, it has not yet been completely solved. Hardly anything is so far known as to the presence of manganese in the plants, animals, waters and soils of Holland; seeds have not generally been studied from this point of view and there are only a few scattered data on the subject.

The author has analysed 48 species of cleaned seeds belonging to the most widely differing families of cultivated plants: the determinations were made on the ash, which was treated twice with sulphuric acid, the persulphate colour-metric test being employed. The following amounts of manganese (in mgm. per 100 gm. of dried seeds) were thus obtained for the most typical plants: *Pinus sylvestris* (Scots Pine) 12.7 — *Phleum* (Cats'-tail Grass) 4.2 — *Alopecurus pratensis* (Fox-tail Grass) 11.6 — Oats 2.3 — *Festuca pratensis* (Meadow Fescue) 15.8 — *Poa pratensis* (Meadow-Grass) 5.3 — Italian ray-grass 4.5 — Wheat 2.8 — Barley 1.14 — Onion 1.2 — Hemp 3.45 — *Beta vulgaris* var. *crassa* (Common beet) 6.6; var. *rapa* 1.95 — Spinach 2.4 — Red Cabbage 6.5 — White Cabbage 2.45 — Turnip 2.1 — Crimson Clover 2.4 — White Clover 1.85 — Red Clover 2.5-2.7 — Lucerne 1.6 — Lupins 17.8 — Beans 1.5 — Peas 0.4 — Flax 10.2 — Celery 1.4 — Carrot 5.8 — Water-Melon 2.5 — Lettuce 2.4 — Chicory 1.7.

From the examination of these data as a whole, it is evident that seeds belonging to the most different families all contain manganese, and in most cases, in the proportion of 2 to 6 mgm per 100 gm. of dry seed. If the manganese content is estimated from the ash, it is in many cases about 50 mgm., and generally a little below 100 mgm. The seeds of few varieties of plants contain a higher proportion of manganese; lupins must however be reckoned among the exceptions, as there are 1700mgm. of this metal present in 100 gm. of ash. This figure is below the percentages given in scientific litera-

(1) See R. November 1921, No. 1097. (Ed.)

ture for the ash of certain "manganese collectors": Oak wood 3.5 % — Birch wood 10-18 % — Beech leaves 9.50 % (in the form of the manganous-manganic oxide) — Lupin leaves 8.96 % (as manganese). If the data for the species of the same genera are compared, it will be seen, that they agree fairly well (see genera *Lolium*, *Allium*, *Brassica*, *Trifolium*, *Vicia*, *Cucumis*). The similarity is however less evident in the genus *Festuca*, and in the genus *Beta* some of the most notable differences occur. If a comparison is made between the leaf data of plants which are sufficiently represented, such as the Festucaceae and Hordeaceae and the Sinapaceae, it will be found that the two first are clearly richer in manganese than the last although in the species of the same families, there are often considerable differences.

151 — **Experimental Researches on the Factors determining Resistance to Cooking in Leguminosae and on the Means employed to Remedy this Defect.** — DE DOMINICIS, A (Laboratorio di Chimica Agraria della R Scuola Superiore di Agricoltura, Portici), in *Annali della R Scuola Superiore di Agricoltura in Portici*, S. II, Vol. 16, p. 31. Portici, 1920.

From the dietetic point of view, the seeds of Leguminosae are described as being easy or difficult to cook according to the greater or less facility with which their consistency is altered by boiling in water. The causes determining this difference are not known, and no systematic attempt has been made to discover them. The question is certainly not one of hereditary character, but depends upon environmental conditions, reaction to which takes certain forms: it is therefore a peculiarity which can only be explained by these given conditions. The author has directed his attention to the causes determining this character and the results obtained are summarised as follows.

The hardness of leguminous seeds from the boiling standpoint depends upon their resistance to the action of water, whether this resistance is natural or artificially produced. The more water a seed can absorb, the more easily is it boiled, and the degree to which it is cooked depends upon the actual amount of water it has absorbed. Thus all the chemical and physical processes occurring during cooking are connected with the amount of the water taken up.

The water resistance of seeds cannot be correlated with any presupposed impermeable mineral deposits due to insoluble calcium combinations, for it can be overcome by alkalis, but not by acids, although the action of acids on the carbonate or silicate of calcium should be more energetic than that of alkalis.

Acids in fact increase this water resistance; oxalic acid has less effect however, than sulphuric and hydrochloric acid although it renders calcium compounds insoluble. This resistance cannot be attributed to the density of the integuments, because if this were lessened by the dissolving effect exerted by the alkalis upon certain given substances, acids should act in a similar manner, or else remain inactive, but in no case should they increase the impermeability of the tissues. Nor can it be regarded as connected

with the action of the ordinary ion present in hard waters upon the insoluble calcium compounds, for the seeds are equally resistant to soft waters, and the hypothesis of the existence of such mineral deposits has already been proved untenable ; moreover salts other than those of calcium and acids themselves have the same effect. For the same reasons the other hypothesis postulating the formation of insoluble calcium compounds at the moment of cooking is equally fallacious. As this water resistance is not overcome by treatment with alcohol or ether, it cannot have any connection with excessively thick deposits of wax or other fatty substances that might possibly occur on the cuticle of the seeds.

The electrolytes penetrate into seeds in proportions different from those in which they are found in solutions, the ratio being larger with acids and alkalis and smaller with salts. Their penetration into seeds is therefore not a case of pure and simple diffusion, however the properties constituting the permeability of plant membranes may be interpreted. The variations produced by the concentration of the solutions upon the amount of the electrolytes incorporated by the seeds depend on the other hand upon a fundamental law governing the adsorption by solid, or colloidal adsorbent surfaces, *e. g.* the adsorption coefficient is not constant but increases as the concentration diminishes.

The substance constituting the seeds and exercising its adsorbent power upon the electrolytes belongs to one of those colloidal forms which arise from the concentration of the dispersive medium, and have the power of restoring it in a measure corresponding with their degree of reversibility. The swelling of the seeds in the presence of water thus consists essentially in a process of imbibition, as is proved by the contraction in volume relatively to the total volume of the seeds and of the absorbed water, the development of heat at the moment of absorption, the optic phenomena accompanying it, the selective power exercised towards liquids, and especially the effect of the electrolytes. The action that may be exerted by the integuments and membranes in this connection is secondary and indirect.

The degree of the reversibility of these colloidal forms is connected with the conditions of the medium in which they have been formed and corresponds with the degree of their affinity to water. The hardness of the seeds is in strict correlation with this degree of affinity to water, although the extent to which it is influenced by the medium and the soil has yet to be determined. Experimentally however hardness is caused or increased in seeds by those special actions that intensify the non-reversibility of the gels, and should have no effect upon the above-mentioned chemical and morphological factors.

The electrolytes act by forming together with the substances of which the seeds are composed adsorption factors having a different affinity to water, or in simpler terms, having a different degree of solubility, solubility being understood in this case to mean the limit of concentration beyond which the substance in the dispersive medium is obliged to coagulate. Acids, acid salts and neutral salts act as coagulants and decrease this solubility ; alkalis and alkaline compounds act in a dispersive manner and

increase it. Thus the alkaline compounds used in cooking decrease the water resistance of the seeds and facilitate the cooking process. At the moment of boiling however the alkalis attack the protein molecule and cause it to disintegrate which leads to the formation of amino-acids and the development of ammonia, sulphuretted hydrogen and carbonic acid. Hence there is a resultant loss of available nitrogen and a danger of the introduction of deleterious substances into the system if such food is eaten. This is a factor of the greatest importance in judging seeds that resist cooking, not only from the dietetic standpoint but also the economic and industrial. It is thus seen how very pernicious are the substances (carbonate of potash and bi-carbonate of soda), now used to remedy the defects of hard seeds due to their excessive water resistance.

- 152 - **A Contribution to the Determination of the Cause of the Formation of Bacteroids in the Nodules of Leguminosae.** — BARTHEL, C. (Bacteriological Laboratory of the Central Station of Agricultural Experiments at Experimentalältet, near Stockholm), in *Annales de l'Institut Pasteur*, Vol. XXXV, No. 10, pp. 634-646 + figs. 6. Paris, October, 1921.

The experiments described in this work form part of a series of studies connected with the morphology and life-history of *Bacterium radicola* which have been carried on for several years in the Bacteriological Laboratory of the Central Station of Agricultural Experiments at Experimentalältet in conjunction with the continuous preparation of cultures of bacteria for the inoculation of the different leguminosae grown by agriculturists.

The results obtained are summarised by the author as follows:

"Our experiments have proved the accuracy of ZIPPER's statement that caffeine has the power of causing the constant formation of bacterioids in solid media. They have however also shown that this property is shared by other plant alkaloids of very different composition. Thus guanidine, pyridine and chinoline all act in the same manner as caffeine, but to a less degree. It is very probable that other alkaloids behave in a similar way, as well as other nitrogenous organic compounds such as hippuric acid.

"As these plant alkaloids always enter into the composition of Leguminosae, it appears to be most likely, that the normal formation of bacterioids in the nodules of this family depends more or less upon the presence of alkaloids in the roots."

- 153 - **Instruction and Investigation in Plant Breeding at the College of Agriculture in the Philippines.** — MENDIOLA NEMESIO, B., in *The Philippine Agriculturist*, Vol. 10, No. 3, pp. 105-107, 1 fig. Los Baños, October, 1921.

PLANT  
BREEDING

The above College of Agriculture offers 2 undergraduate courses and 1 advanced course in plant genetics. Each covers a period of six months.

*First course:* this consists of lectures and laboratory work and is modelled upon the first two undergraduate courses at Cornell University. It aims at giving students a fundamental understanding of the facts and laws underlying the phenomena of heredity and variation in their widest sense, and the relation of these phenomena to environment.

*Second course*: this deals with the methods and technique of plant-breeding with special reference to the Philippines and the Tropics.

*Third course*: elementary biometry.

The attention of the College of Agriculture has not been devoted only to instruction. Much practical work has been done in encouraging and carrying out experiments in selection and crossing, especially with rice, maize and sugar-cane which are among the most important crops of the Philippines.

- 154 - **Genetic Behaviour of the Spelt Form in Crosses between *Triticum Spelta* and *Triticum sativum*. The Possibility of obtaining Synthetic Forms of Wheat by Crosses between Two Spelts.** — LEIGHTY, C. E., and BOSHNAKIAN, S., in *Journal of Agricultural Research*, Vol. XXII, No. 7, pp. 335-364. Washington, November, 1921.

In the work described in this article 3 characters were taken into consideration: the shape of the glume, the brittleness of the rachis and the adherence of the grain. These characters are to a great extent linked.

**THE OUTER GLUME OF *Triticum sativum*.** — This is as a rule soft with a somewhat pointed apex and only occasionally weakly keeled along the entire length. About 0.5 to 1 mm. above the point of attachment there is a wrinkle or depression; the base is rather narrow and is very weakly attached to the rachis. In *T. spelta* on the other hand the glume is stiff and thick and has a very blunt apex. It is strongly keeled and has no depression above the base, which is wide and firmly attached to the rachis. Further in the spelt the rachis is brittle and the grains adhere firmly, whereas in wheat the rachis is much more tenacious and the grains are easily detached. These three characters, as stated above, are linked as if dependent on factors united in a single chromosome. The occurrence of crossovers, if it ever occurs, must be very rare.

In the 2nd and subsequent filial generations of *Spelta*  $\times$  *sativum* there are many forms intermediate between the two parents.

In order to record the degree of inheritance of Spelt characters the authors have made an arbitrary scale of values ranging from 1 to 10, in which 1 represents typical spelt, and 10 typical wheat with no spelt characters.

The hybrids of the  $F_1$  are slightly intermediate in form, but much more like the spelt than the *sativum* parent. They grade from 4 to 7 and have all the characters of a spelt, except that the spikelets are somewhat more open and the glumes are less adherent to the grain. In the  $F_2$  the forms range from the typical wheat to the spelt, viz., from 1 to 10.

The frequency curve of these forms is of a special type, more individuals being as a rule found at the extremities than near the centre as is seen from Table I.

As it is impossible to distinguish the homozygous spelts from the heterozygous, 2 groups only have been made in which all the spelt and speltoid forms are included (classes 1-9 inclusive).

TABLE I. — *Number of Plants of the F<sub>2</sub> Spelta × sativum classed in 10 Categories.*

Series	Crosses	Number of individuals in class										Total
		1	2	3	4	5	6	7	8	9	10	
13255 <sup>a</sup>	<i>Spelt</i> sel. 13440 × Dale Gloria sel. 13401 . . . . .	17	10	9	5	4	1	3	1	2	21	73
13260 <sup>a</sup>	<i>Spelt</i> sel. 13438 × Turkey sel. 13389	17	13	5	5	2	3	2	—	2	14	63
13263 <sup>a</sup>	Dale Gloria sel. 13401 × <i>Spelt</i>	5	3	2	3	1	—	2	2	—	7	25
3049 <sup>a</sup>	Black Bearded <i>Spelt</i> × Early Red Chief . . . . .	19	7	5	—	3	4	3	5	6	29	81
3085 <sup>a</sup>	Black Bearded <i>Spelt</i> × Jones Longberry . . . . .	9	8	4	2	4	—	4	2	4	13	50
13124 <sup>a</sup>	<i>Vulgare</i> (C. I. 3338) × <i>Spelt</i> sel. 13437 . . . . .	9	8	4	9	7	4	3	5	7	20	76
13125 <sup>a</sup>	Crimean (C. I. 3340) sel. 13351 × <i>Spelt</i> sel. 13437 . . . . .	6	3	9	3	4	2	5	5	4	9	50

The proportions between *spelta* and *sativum* forms thus approximated to the monohybrid ratio of 3 : 1. The proportion of homozygous forms to heterozygous forms of spelt would therefore be 1 : 2 : 1, as is shown by the *F<sub>3</sub>* generation of 2 *F<sub>2</sub>* families, 13 260<sup>a</sup> and 13 255<sup>a</sup> (see Table II). TABLE II. — *Number of F<sub>2</sub> Plants from Series 13 260<sup>a</sup> and 13 255<sup>a</sup> which proved be Homozygous Spelts, Heterozygous forms and Homozygous Wheats (1 : 2 : 1) when tested in the F<sub>3</sub> Generation (1 : 2 : 1).*

Nature of data	13260 <sup>a</sup> <i>Spelt</i> × Turkey				13255 <sup>a</sup> Dale Gloria × Turkey			
	Homozygous <i>Spelts</i>	Heterozygous	Homozygous <i>Wheats</i>	Total	Homozygous <i>Spelts</i>	Heterozygous	Homozygous <i>Wheats</i>	Total
Obtained . .	8	13	9	30	7	14	12	33
Calculated. .	7.5	15.0	7.5	—	8.2	16.5	8.2	—
Deviation. .	0.5	2.0	1.5	—	1.2	2.5	3.8	—

The ratio 3 : 1 does not always occur. In the 2 families 13 126<sup>a</sup> (Giant Square head × spelt) and 3019<sup>a</sup> (Spelt × Salt Lake Club), for instance, the wheat types were very low (See Table III); in fact the proportion between the spelt forms and the wheat forms is better represented by the ratio 15 : 1 (See Table III).

On examining the *F<sub>3</sub>* generation of 27 *F<sub>2</sub>* plants, it was found, that 12 of these had produced only spelts, 2 plants yielded only *sativum* types, and the remaining 13 produced progeny of mixed forms.

TABLE III. — Degree of Spelting and Proportions of Spelts and Wheats Obtained in the  $F_2$  Generations of *Spelta*  $\times$  *sativum* Crosses which did not segregate in the 3 : 1 Ratio.

Series	Degree of spelting in class										Total	Number of plants				Deviation	Probable error
	1	2	3	4	5	6	7	8	9	10		Obtained		Calculated			
												Spelta	Sativum	Spelta	Sativum		
I326*	12	7	7	6	9	8	3	6	12	4	74	70	4	69.4	4.6	0.6	1.49
3019*	27	15	9	7	3	5	2	5	8	2	83	81	2	77.8	5.2	3.2	1.49

We thus have the proportion, homozygous *Spelta* 7 : heterozygous form 8 : homozygous *sativum* 1, as it should be according to the proposed 15 : 1 ratio.

Assuming that the spelt parent in this particular cross carries two spelt factors  $S_2$  and  $S_1$ , the two first generations will consist of the following genotypic forms :

$P_1$ (Giant Squarehead)	$S_1S_1S_2S_2$	$\times$	$S_1S_1S_2S_2$	(Winter spelt)
<i>T. sativum</i>				<i>T. Spelta</i>
$F_1$ . . . . .	$S_1S_1S_2S_2$			
	(Speltoid)			
$F_2$ (1)	$S_1S_1S_2S_2$	(1)	$S_1S_1S_2S_2$	(4) $S_1S_1S_1S_2$
		(2)	$S_1S_1S_2S_2$	(2) $S_2S_1S_2S_2$
		(1)	$S_1S_1S_2S_2$	(2) $S_1S_1S_2S_2$
		(2)	$S_1S_1S_2S_2$	
		(1)	$S_1S_1S_2S_2$	
Total: 1 <i>T. sativum</i>		15 <i>Spelta</i>		

In the  $F_3$  the theoretical behaviour of each of the  $F_2$  plants would be as follows :

Group	$F_3$ Genotypes	Phenotypes of the $F_2$ and their Behaviour in the $F_3$
A	(1) $S_1S_1S_2S_2$	1 <i>sativum</i> will yield <i>sativum</i> only
B	(1) $S_1S_1S_2S_2$	
	(2) $S_1S_1S_2S_2$	7 <i>Spelta</i> will yield <i>Spelta</i> only
	(2) $S_1S_1S_2S_2$	
	(2) $S_1S_1S_2S_2$	
	(1) $S_1S_1S_2S_2$	
C	(4) $S_1S_1S_2S_2$	4 <i>Spelta</i> will segregate in $F_3$ into <i>Spelta</i> : <i>sativum</i> in the ratio 15 : 1
D	(2) $S_1S_1S_2S_2$	4 <i>spelta</i> will segregate in the ratio 3 : 1.
	(2) $S_1S_1S_2S_2$	
		8 unstable forms

When the  $F_3$  plants were examined a close approximation was found to the above-mentioned theoretical ratios, even as regards the genotypes which segregated in the 15 : 1, and the 3 : 1 ratios respectively.

In this connection it should be specially noticed that the same genotype of *Spelta*, when crossed with different varieties of *sativum*, can give two types of segregation 15 : 1 and 3 : 1. The authors try to account for this phenomenon by assuming that the spelt parent carried 2 spelt factors  $S_1$  and  $S_2$  and that some of the wheats used in the crosses carried an inhibiting factor  $I$ . In the presence of the latter factor, the ratio would be about 3 : 1, in its absence, the ratio would be 15 : 1.

Further the existence of determinants (modifiers) accentuating or attenuating the spelt characters has been clearly shown by the authors in the course of this work, thus explaining why heterozygous spelts of the  $S_8$  type can produce very different frequency curves. Thus for instance plant 13 260<sup>a</sup>-3 produced individuals mainly of classes 8 to 9, while plant 13 260<sup>a</sup>-6 produced its spelts in classes 1 and 2 only ; in the first case, there was a genetic factor attenuating the spelt character, and in the second a factor accentuating it. The presence of these factors, as may be readily understood, alters the Mendelian ratios between the *Spelta* and *sativa* forms and the combined effect of the factors accentuating and attenuating the *Spelta* character can produce some very complicated segregations.

PRODUCTION OF SYNTHETIC WHEATS BY CROSSING TWO SPELTS AND OF SYNTHETIC SPELTS BY CROSSING TWO WHEATS. — The authors have frequently obtained synthetic spelts in interspecific crosses in wheat. No indication has been observed as to the possibilities of producing true wheats in crosses between two different non-wheat cereals. It is theoretically possible, however, that such forms will be produced in crosses between certain kinds of spelts, as will be seen from the results of one of the experiments discussed in this paper. In the cross 13 126<sup>a</sup> it was shown by the authors that 2 spelt factors  $S_1$  and  $S_2$  were involved and that there were present in the  $F_2$  5 genotypic forms namely:

$$S_1S_1S_2S_2 - S_1s_1S_2S_2 - S_1S_1S_2s_2 - S_1s_1S_2s_2 - s_1s_1S_2S_2$$

As long as the forms are allowed to be selfed, as they are in nature, no *sativum* forms will ever appear, but in a number of crosses between these 5 forms, a certain proportion of wheat should occur in the following manner:

- 1) Crosses producing no wheats :  $S_1S_1S_2S_2 \times$  any other genotype  
 $- S_1s_1S_2S_2 \times s_1s_1S_2S_2 - S_1S_1S_2s_2 \times s_1s_1S_2s_2 = S_1S_1s_2s_2$ ;
- 2) Cross where one out of every four  $F_2$  plants will produce 6  $\frac{1}{4}$  % wheats :  $S_1S_1S_2s_2 \times S_1s_1S_2S_2$  ;
- 3) Crosses where half of the  $F_1$  plants produce 6  $\frac{1}{4}$  % wheats :  
 $S_1S_1s_2s_2 \times S_1s_1S_2S_2 - S_1S_1S_2s_2 \times s_1s_1S_2s_2$ .
- 4) Cross where all  $F_1$  plants will produce 6  $\frac{1}{4}$  % wheats :  $S_1S_1s_2s_2 \times s_1s_1S_2S_2$ .

It is easy to understand how the wheat (*sativum*) character, being distinctly hypostatic, may be carried concealed from generation to generation

by the spelt type. How can the spelt type, which is so pronouncedly epistatic to the wheat character, be carried by a wheat without being manifested phenotypically? The explanation is simple. It was shown that modifying determinants are involved in these crosses. Common wheats occasionally carry modifiers which dilute the spelt character to the extent of grouping all the  $F_2$  spelts into class 9. If these diluting factors are reduced to a homozygous dominant condition, they can well produce forms of spelt, identical or almost identical in appearance with wheat.

From a number of wheat  $\times$  wheat crosses (where one of the parents was a rust-resistant variety of winter-wheat and the other was Preston, Marquis, or Haynes Bluestem), over 20 spelts were found among the  $F_2$  hybrid plants, though there were no spelts in the  $F_1$ , their absence being due to an inhibition in the parent plant carrying the S factor.

These observations show that common wheats may carry the spelt factor, which is, however, unable to express itself because of the presence of one or more diluting or inhibiting factors.

The production of synthetic spelts in these *sativum*  $\times$  *sativum* crosses is similar to the synthetic production of *Triticum dicoccum dicoccoides*, the "Wild Wheat" of Palestine by the *vulgare*  $\times$  *durum* cross. The wild character, consisting of a number of interdependent specific characters, is strongly dominant over both the *vulgare* and the *durum* types just as the spelt type is dominant over *sativum*, yet in both instances, the character showing strong dominance towards either of the parental forms was carried by one of the parents together with a factor inhibiting in one case the "wild" and in the other, the spelt, characters.

**155 - Variation and Correlation of Characters Among Rice Varieties Cultivated in the Philippines.** -- TORIBIO VIHAR, in *The Philippine Agriculturist*, Vol. X, No. 3, pp. 93-104, bibliography of 24 works. Los Baños, October 1921.

**OBJECT OF THE WORK.** -- The investigation of which an account is given in this paper was conducted mainly as a basis for the selection of desirable varieties and to find answers to the following questions:

- 1) Are the late-maturing varieties heavy grain yielders?
- 2) Do tall varieties produce more grains than short?
- 3) Is there any relation between the length of the leaves, the length of the panicles, and the length of the grains on the one side, and the reproductive power of the plant on the other?
- 4) What relation have the width of the leaves, and the width of the grains to the productive power of varieties of rice?
- 5) Have the number of nodes and the number of spikes in the panicle anything to do with the grain yield?
- 6) Do tall varieties mature late?
- 7) Are varieties with long leaves, long panicles and long grains late in maturing?
- 8) Have the number of nodes and the number of spikes in the panicles any relation to the length of the growth period?
  - 9) Have the width of the leaves and the width of the grains any relation to the growth period?
- 10) Is it true that varieties producing much straw require more time to mature?

The work was carried on during 1919-1920 in the rice-fields of the College of Agriculture and in those belonging to the Philippine Experiment Station farm.

**MATERIALS AND METHOD.** — For the study of variation and correlation 85 varieties were used: of these 16 are upland and 69 lowland — 30 awned and 55 awnless — 7 glutinous and 78 non-glutinous — 64 white — 1 black — 4 red — 15 mixed (of which some are undoubtedly hybrids).

TABLE I. — *Growth Period and Length of Culms.*

Growth period		Length of culms	
Days	Frequency	Centimetres	Frequency
100-120	3	80.00-96.66	21
121-140	21	96.67-113.33	20
141-160	21	113.34-130.00	25
161-180	22	130.01-146.67	13
181-200	16	146.68-163.34	3
201-220	2	163.35-180.01	3
Mean = 158.24 days		Mean 98.72 cm	

For the other values, it is sufficient to give the means — length of panicles = 22.50 cm.; number of spikes per panicle = 10.73; number of nodes per panicle = 8.11; width of broadest leaves 11.17 mm. — length of longest leaves 52.48 cm.; average width of 20 grains, 3.25 mm.; average length of 20 grains, 8.33 mm.; weight of straw per plant = 10.78 gm.

After giving the biometric data, the author considers the question of the coefficient of correlation between the most important characters. He obtained the results given in Table II, from which the following conclusions may be drawn:

- 1) The longer the time varieties of rice take to mature, the more grain they will yield.
- 2) Tall varieties produce more weight of grains than short.
- 3) Long leaves, long panicles and long grains are varietal qualities indicating high yielding power. These characters are also associated with the length of [the growth period.
- 4) There is no correlation between yield and growth period on the one hand and length and width of grains on the other. There is no connection between yield, growth period and number of spikelets per panicle.
- 5) The number of nodes in the panicle is strongly associated with yield.
- 6) Varieties producing much straw are not necessarily heavy yielders, but they are generally late maturing.

Of the 19 pairs of characters studied in this investigation, 4 were included in JACOBSON's work viz. growth period and yield of grains; length of culms and yield; length of grain and growth period; width of grain and growth period. The results obtained by the author substantiate those of JACOBSON in all respects but one. Width of grains and growth period were found by JACOBSON to be negatively correlated; in the author's work they were found to have no correlation at all.

TABLE II. — *Coefficient of Correlation between the Most Important Characters.*

Yield and growth period . . . . .	0.5613 ± 0.0498
Yield and length of culm . . . . .	0.4616 ± 0.0579

156 - Leaf-Tissue Production and Water Content in a Mutant Race of *Phaseolus vulgaris* as compared with the Parental Race. — HARRIS, A. J., in *The Botanical Gazette*, Vol. LXXII, No. 3, pp 151-162. Chicago, Illinois, September 1921.

The objects of these investigations were to determine to what extent seedlings which are morphologically aberrant in the race to which they belong differ also from the normal seedlings in their physiological characters, in so far as these can be measured by the capacity for the production of tissue.

The author used as material a completely fixed teratological race of *Phaseolus* having the character of possessing 4 cotyledons. The tissues of this race (especially those of the primordial leaves) were compared with the tissues of the original line.

The biometric data fall into 3 groups:

- 1) a series of weighings of primordial leaves unclassified as to their number;
- 2) a series of weighings of primordial leaves classified with respect to their number;
- 3) a series of weighings of total epicotyledonary tissue.

*Group 1.* — The total weight of primordial leaf tissue in the abnormal seedlings is compared with the total weight in the control plants irrespective of the number of primordial leaves formed by the individual plants of the tetracotyledonous race. The total number of leaves per plant was determined separately and the following figures obtained for the 4 samples: 226 = 4.07; 227 = 4.15; 228 = 4.00; 229 = 3.91. The data are given in Table I.

TABLE I. — *Mean Green Weight per Plant and per Leaf.*

No of Plants	Per plant				Per leaf			
	Abnormal	Normal	Difference	Difference in %	Abnormal	Normal	Difference	Difference in %
226	0.6991	0.7516	— 0.0525	— 6.9 %	0.1718	0.3758	— 0.2040	— 54.2 %
227	0.6972	0.7607	— 0.0635	— 8.3	0.1680	0.3804	— 0.2124	— 55.2
228	0.6323	0.7568	— 0.1245	— 16.4	0.1542	0.3784	— 0.2242	— 59.2
229	0.7012	0.6862	+ 0.0150	+ 2.1	0.1793	0.3431	— 0.1638	— 47.7

The results show, that in 3 out of 4 cases, the green weight of the 4 primordial leaves of the tetracotyledonous race is lower than that of the 2 primordial leaves of the dictyledonous strain. The percentage differences range from + 2.1 to —16.4 with a general average of —7.37. When the comparison is made on the basis of the mean weight per leaf, the primordial leaf of the abnormal seedling is found to be on the average 54.22 per cent lighter than the leaf of the normal seedling.

The percentage differences for dry weight of primordial leaves are less, varying from —1.6 to —18 % with a general average of —10.9 %. As regards the mean dry weight per leaf, the weight for tetracotyledonous plants was lower than for dicotyledons, the general average percentage difference being —55.92.

*Group 2.* — In order to make the comparative work more complete, the author made a minute examination of the relationships by considering individually the results obtained for abnormal seedlings with varying numbers of primordial leaves (2 to 7). The data show that: the difference between the total weight of primordial leaf tissue in the abnormal and the normal seedling decreases with the increase in the number of leaves in the abnormal plant, but the tetracotyledonous plants always produce a smaller total weight of leaf-tissue than the normal plants. The difference is greater when the comparison is made on the basis of dry weight. These data are summarised in Table II.

TABLE II. — *Differences in the Green Weight and Dry Weight of the Normal and the Abnormal Types.*

No of Plants	Difference of Green Weight	Difference of Dry Weight
2	— 31.55	— 32.55
3	— 20.74	— 25.54
4	— 11.97	— 16.34
5	— 8.60	— 13.78
6	— 3.10	— 7.93

*Group 3.* — The results obtained by a comparison of the total weight of tissue produced above the cotyledonary node confirm what has already

been ascertained as regards the primordial leaves alone. The green weight and the dry weight are highest in normal plants, the percentage differences ranging from -7.6 to -29.4 for the green weight, and from -10.1 to -30.5 for the dry weight.

Thus the mutant race is distinguished not merely by striking morphological differences, but by physiological differentiation as well.

**157 - Production of Varieties of Bean with Mottled Seeds.** — BLARINGHEM, L., in *Comptes rendus de l'Académie des Sciences*, Vol. 173, No. 10, pp. 666-668. Paris, October 1921.

In 1922 the author received from the Museum of Natural History 6 small, glossy, black seeds of *Vicia Faba* L. var. *pliniana*. These were sown at the Laboratory of Meudon (Seine et Oise), at the end of April, and produced 5 plants of uniform characters which bore seeds exactly similar to the sample. In the autumn of the same year, the author planted the seeds from a single plant of *V. Faba* var. *equina* taken from a crop of beans at Locon (Pas de Calais). The two lines were crossed on May 13; the pure-bred progeny when examined in 1913 and 1914 showed no variation from the original type.

The author attributes to crossing the variations described later.

The parent plants differed in many of their characters: *V. Faba equina* grows vigorously, producing 2-3 strong, grooved, hollow stems of equal length (120 cm.), 15 mm. in circumference at the base. The bunches of compact flowers give place to 3 to 6 smooth pods 10-12 cm. in length; each fruit contains 4-6 oblong seeds of average size (12 mm.  $\times$  8 mm.  $\times$  6 mm.), of a uniform light grey colour. *V. Faba pliniana* is a slender plant with one short main stem which is succeeded by late secondary shoots that are usually sterile. The stem is partially hollow, little grooved and measures 7 mm. at most round the base. It bears few flowers which grow two or three together and are succeeded by very small, pubescent pods with a slender tip. The fruits never exceed 5 cm. in length and generally contain 2 (never more than 4), black, oblong seeds of the size of a pea (6 mm.  $\times$  4 mm.  $\times$  3 mm.).

The crosses were made in the hope of obtaining xenia, but no sign of this phenomenon could be discovered. The cross-fertilisation (*pliniana*  $\times$  *equina*) of 3 flowers produced 2-1-0 seeds, and by the reciprocal cross (*equina*  $\times$  *pliniana*) also of 3 flowers, 3-1-1 seeds were obtained. The 8 seeds were sown in March 1914 and produced plants intermediate between the parents as regards length of stem and size of flowers and fruits. The stems were numerous and leafy, perhaps owing to the care taken in replanting the seedlings. The plants were gathered in August 1914 but could not be examined until August 1918: all the pods were hairy and had a curved beak; they contained 214 well-shaped, perfectly similar seeds. Their dull brown colour was no doubt more intense than when they ripened, for it has been found that bean seeds, whether green or yellow, become darker in the course of some years. When sown the following spring, these beans produced 92 plants whose progeny were followed until 1921.

In the second generation ( $F_2$  — 1919) the segregation of the black-grey colour factors in the seeds appeared to take place regularly, since 30 *pliniana*  $\times$  *equina* seeds produced 7 hybrids with grey seeds and 23 brown or shaded seeds : 62 *equina*  $\times$  *pliniana* seeds produced 15 hybrids with grey seeds and 47 with brown seeds : the percentages of the grey recessives (23.5 and 24.3), being near the theoretical number, 25. The brown dominants were however not at all uniform, ranging from graduated shades of mottled grey to glossy black. Similarly 10 out of 47 of the *equina*  $\times$  *pliniana* hybrids were found to have a light ground mottled with yellow or brown. As a general rule the seeds borne by a single individual are alike: two plants of the  $F_2$  however produced some pods in which the black seeds were in striking contrast to mottled seeds; an instance of segregation giving rise to a mosaic which the author has not since observed.

The proportion of plants with mottled seeds was far larger in the  $F_3$  (1920). The 10  $F_2$  individuals with mottled seeds only produced seeds of this colouring; the 22 grey-seeded recessives produced 155 plants with grey seeds and 4 with mottled seeds, these individuals were no doubt the descendants of an  $F_2$  plant with seeds but slightly mottled and hence passed over in 1919. In addition, a new character that had hitherto escaped the author's notice was clearly manifested in the progeny of some of the  $F_2$  plants. This consisted in the presence of small brown dots on a grey background which were usually most numerous round the hilum and periphery of the seeds.

In the  $F_3$  (1920), the relative proportions due to segregation in the brown hybrids ( $F_2$ ) were as follows :

	grey	Seed plants		
		black	mottled	spotted
<i>pliniana</i> $\times$ <i>equina</i> (23). . .	62	45	113	6
<i>equina</i> $\times$ <i>pliniana</i> (47). . .	93	52	177	4

The 1921 ( $F_4$ ) crops confirm these results, the progeny of the grey-seeded recessives all produced grey seeds with the exception of two lines in which there was a halo of brown spots surrounding the hilum. The plants resulting from the black seeds were rather weak and somewhat infertile. Half their seeds were black, the other half consisting of grey, black, mottled and spotted seeds in the proportions found in the  $F_3$ . The spotted seeds of the  $F_3$  chiefly produced plants with similar seeds; only 10 % showed a throwback to grey or black colouring. Out of 28 plants grown from spotted seeds 13 bore spotted, 3 mottled, and 12 grey seeds.

On the other hand, a cross made at the end of June 1919 between late ( $F_2$ ), individual of *pliniana*  $\times$  *equina* and a green-seeded *Vicia Faba* (Windsor bean), produced in 1920, shaded, intermediate, but flat beans, of which the 12 descendants in 1921 were composed of 2 recessives with

green seeds, 4 plants with brown seeds and 6 with mottled. It is remarkable that here again *the proportion of mottled seeds exceeds that of the brown or grey-seeds.*

*To sum up:* crosses effected between various divergent kinds of *Vicia Faba* show that in seeds *brown is dominant to grey or green.* The *pliniana* line imparts to the hybrids (after the second generation), the *new characters of mottles or spots*, which persist in a good many of the progeny and appear even more fixed than the brown character of the parent. There are many fixed varieties of *Phaseolus* characterised by mottling, spots or shaded areas round the hilum, so no doubt similar varieties of *Vicia Faba* could also be obtained, if there were any market demand for them.

158 - **Cotton Selection: Method Adopted in Egypt by the Sultanic Agricultural Society** (1). — FREEMAN GEO. F., in *Sultanic Agricultural Society, Technical Section Bulletin* No. 3, pp. 1-16. Cairo, 1920.

The chief types of cotton, such as American Short Staple, Indian Short Staple and Sea Island, have in all probability their origin in conscious or unconscious selection from different wild species. The several varieties within these types have originated from sports, mutations or hybrids that have been grown in separate cultures or have gained ascendancy through local climatic selection.

Since however crossing takes place freely between the different types within a species, very few commercial varieties are even approximately pure. When to this is added the mechanical mixing of seeds that occurs at the ginning plants and store-houses or through volunteer cotton in the field, it is easy to realise the difficulty of the task of the cotton selector whose object is not only to discover or produce high yielding varieties of desirable quality, but also to secure and maintain uniformity in his product.

SELECTION OF ORIGINAL, MOTHER PLANTS. — a) *Material.* — At least two or three acres are planted with the best available seed of the variety to be improved in such a manner as to facilitate the observation of the individual plants.

b) *Selection Based on Vegetative Characters.* — The type that is to be the object of selection is first determined. For this purpose a set of arbitrary standards is chosen for each of the characters (shape of boll, height of plant, branches, etc.), in order to serve as a basis of comparison.

A thousand or more plants which are true to the type of the variety in all characters considered must be examined. Each plant is given a serial number and its description is written on a printed blank. That used in 1919 was as follows:

(1) See Orig. Article of W. L. BALLS, "Studies on the Cotton Plant of Egypt," in *R. Aug.* 1915, No. 1096. (Ed.)

COTTON — *Description of Selected Plant.*

Locality . . . . . Date . . . . .  
 Variety . . . . . Plant No. . . . .  
 Diameter of space occupied . . . . . dem.  
 Height . . . . . dem.  
 Habit: open — shut — dwarf — bushy.  
 Leaves: large — medium — small.  
 Vegetative Branches: Number . . . . .  
 Bolls: Size — large — medium — small.  
 Boll: Number . . . . . Shape No. . . . .

Locules	2	3	4	5

Seed Cotton: Total weight . . . . . weight per boll . . . . .  
 weight of seed . . . . . % lint . . . . .  
 weight of lint . . . . . weight of 100 seeds . . . . .  
 Lint index . . . . .  
 Notes . . . . . Length of lint . . . . .  
 Seeds per boll . . . . .

c) *Selection Based on Provisional Estimate of Lint Length and Strength.* — The length and strength of the lint are roughly estimated in the field. If the lint from apparently normal bolls is weak or too short the plant is at once rejected.

d) *Selection Based on Laboratory Studies.* — The laboratory studies are based upon the different picking of the same plant put together, and are carried out in the following order.

1) A choice is made of seeds for microscopic or physical studies: the material is divided into 10 lots, from each of which is taken at random a sound locule; the middle seed is removed, great care being taken to separate it with its own lint.

2) The cotton seed is weighed (excluding the sample of 10 reserved seeds).

3) The seed is ginned and the seed and lint are put into separate pockets of the bag.

4) The samples of lint are submitted to a cotton expert to distinguish the three classes "bad", "typical", "superior". All the samples classified as bad are discarded.

5) The lint is weighed and its % calculated.

6) The representative sample of seeds is weighed and the lint index calculated by the following formula:

$$\frac{\% \text{ lint} \times \text{weight of 100 seeds} \times 100}{\% \text{ seeds}} = \text{lint index}$$

(It is convenient to use tables previously prepared).

7) The seeds of the plants classified as "typical" or "superior" in lint characters and which have shown themselves typical in morpho-

logical characters are then studied as regards : amount and colour of the fuzz, the shape and colour of the seed etc. It is best to use for comparison type samples placed in series and referred to by number thus : fuzz color 6 ; fuzz distribution 4 ; beak 5 ; shape 8 ; seed-coat markings 3 ; seed-coat colour 5. The range of the type of the variety in each of these characters having been determined, any plant falling outside the variety type-group should be discarded.

8) The seeds of those plants which are true to the type of the variety and are classed as excellent by the expert and also show agricultural promise (earliness, good yield, etc.), are retained for planting in pedigree plant plots the following year. The ten seeds reserved from these plants are subjected to careful laboratory studies ; 1) measurements of the lint length by combing and measuring the circumference of the lint halo, in special cases, the measures of individual fibres are also taken. Breaking strength and elasticity are determined on 100 fibres from each plant — 3) the relative fibre diameter and twist are determined microscopically on 20 fibres. These characters are all recorded and kept for comparison with the offspring of the selected mother plants grown in the pedigree plant plots the following year.

**PEDIGREE PLANT PLOTS.** — *First year* : the seeds of each mother plant are sown separately in the pedigree plots. When the plants are well established they may be thinned to one plant in the hill. During the blooming season, all the fresh flowers in each of the plant plots are counted daily ; the data thus obtained shows the earliness of the strain. Throughout the growing season, each plot is studied with regard to its uniformity in vegetative types and to all characters indicative of its agricultural value, special attention being paid to : the number and position of the vegetative branches ; the number and position of the flowers ; the length and number of the nodes of the fruiting branches ; the type and quantity of the leaves ; size and shape of the bolls ; the number of locules ; and the manner of opening of the bolls.

As the plants develop and begin to bloom, all " off type " plants should be pulled up, the reason for their destruction being given in the records of the plot.

When the first bolls open, the plant plots must be examined carefully, and those having bad vegetative characters, or few bolls per plant, or shewing late development should be rejected. From each of the remaining plots a representative sample should be picked on which are recorded lint length, weight of lint per boll, lint index and seed weight. All plots below the average in these respects are at once rejected.

From the remaining plots the plants are picked separately at harvest time. The final height-number of vegetative branches ; boll-shape number ; number of bolls opening ; average weight of seed cotton per boll ; percentage of lint ; weight of 100 seeds ; lint index ; lint length and quality of lint, as judged by the expert, are recorded for each plant.

These data are then assembled to show the distribution and average value of the different vegetative characters for the plants of each plot.

These distribution curves may then be compared with the corresponding characters of the parent plants in order to ascertain the parental stocks which were able to transmit their special characters in a high degree and average to the population of their offspring.

After the completion of these studies, the most promising individual plants of the superior plots are retained for sowing in plant plots the following year.

*Second year.* — The plant plots are sown, treated and studied exactly as in the first year; all plots that do not maintain the high standard exhibited the first year are eliminated.

In order to secure pure close-fertilised seed from the most promising plots, bags are used. These were made by the author from mosquito netting and do not hinder the respiration or transpiration of the flower as is the case with bags of paper or muslin: A piece of netting 5 by 6 inches is required for each, this is folded and sown up, so as to form a bag 3 by 5 inches; at the open end is attached a piece of thin copper wire about 4 or 5 inches long which keeps the bag in position, being twisted two or three times round the pedicel. The bag may be put on as soon as the pedicel is long enough to allow the bag to be closed beneath the bracteoles.

The exact size of the bag (which varies according to the variety of cotton-plant), must be such as to allow the petals to develop normally, but not to unroll completely. The petals thus form a loose envelope enclosing and protecting the stamens and pistils so that self fertilisation is insured.

*Third year.* — The close pollinated seed from the most promising individual plants and the superior plots of the second year are again sown and studied in the same manner, all off-type or inferior plants or unsatisfactory plots being discarded. The seed of each plot remaining after this eliminating process, is collected together, and kept for planting the following year in *pedigree increase plots*.

**PEDIGREE INCREASE PLOTS.** — *First year.* — These must be carefully watched in order to eliminate all off-type or interior plants. The study of the agricultural, vegetative and lint characters is made as before, but owing to the large number of plants, a certain number only forming a representative sample, are examined. At the end of the season the less promising plots are rejected and the seed of the very best is sown in the larger pedigree increase plots of the next year.

*Second year.* — The same operations are carried out as in the first year. At the end of the season, a further selection is made whereby only the strains which have passed all the 6 elimination tests are retained. The seeds of these strains will by this time have multiplied to such an extent as to admit of planting in large scale increase fields

In short, the operations may be grouped under the following headings:

- 1) Selection of original mother plants
- 2) Pedigree plant plots: First year
- 3) Pedigree plant plots: Second year
- 4) Pedigree plant plots: Third year

- 5) Pedigree increase plots: First year
- 6) Pedigree increase plots: Second year
- 7) Pedigree fields.

The plan is thus designed to give a continuous supply of seed pure to type and never more than 6 years removed from a single selected mother plant. If artificial hybridisation becomes desirable, the  $F_2$  plants will serve as the starting point for plant selection in the same manner as has been above described for field selection. Here selection is made by keeping in mind the combination of characters desired in the new type.

**CEREALS  
AND  
PULSE CROPS**

159 — Varietal Trials with Spring Wheat in North Dakota, U. S. Comparative Grain Yields and Milling and Baking Qualities. — STOA, T. E., in *Bulletin* 149, *Agricultural Experiment Station, North Dakota Agricultural College*, pp. 1-55, table XXXIII, figs. 4 Aug 1921.

The average acreage cropped with wheat in North Dakota for the 10 years period 1910-19 was 7 767 500 acres, and the average acre yield during that period was 10.5 bushels.

Varietal trials have been conducted at 7 Experiment Stations in this State. The average annual precipitation at these Stations ranges from 13.77 in. at Hettinger (S. W.) to 23.62 in. at Fargo (S. E.) and the average seasonal precipitation (April to July inclusive) ranges from 8.05 inches at Hettinger and 8.12 in. at Langdon (N E) to 12.67 in. at Fargo.

GRAIN YIELDS. — Comparative data on grain yields for the two main classes of wheat, namely, common (*Triticum vulgare*) and durum (*T. durum*) are given with reference to the several Sub-stations concerned. The class and group separations employed are as follows:—

1) *T. vulgare*: Fife Group. — Red Fife, Power, Glyndon, Marquis, Ghirka Spring, Kitchener, Ruby, Red Bobs; Bluestem Group. — Haynes, Dakota; Preston Group. Preston Pioneer, Kota, Miscellaneous. Prelude, Humback.

2) *T. durum*: Amber Durum Group. Kubanka, Arnautka, Monad, Acme, Mindum, Kahla, Peliss, Golden Ball. Red Durum Group, D. 5 (Durum No. 5), No. 58 (C. I., No. 5618).

Of the *T. vulgare*, Marquis is distinctly superior to all other commercial varieties, for the Eastern and Southern sections of the State. In the central and south-western sections, Power gave a slightly superior yield, but the difference between the two is negligible. Stem rust (*Puccinia graminis*, has been less frequent in the western than in the eastern sections.

A comparison is made between the average yields (in bushels per acre) of the best varieties of *T. vulgare* grown at each station from 1913 to 1920, for 3, 4, 5, 7 and 8-year periods respectively. Taking for example the results for the 7-year period in the S. E. and N. W. the two outstanding varieties, Marquis and Power (Fife group), gave for the 7-year period in the S. E. area (Fargo), 21.7 and 18.8 bus. per acre respectively and in the N. W. area (Williston), 27.2 and 27.9 bus. respectively. Of the Bluestem group for a similar period in the S. E. Dakota and Haynes both gave 15.5 bus. per acre and in N. W. 26.8 and 25.5 bus. respectively. Of the Preston group

the var. Preston gave for a similar period 18.5 bus. (S. E.) and 26.6 bus. (N. W.).

A similar comparison is made between the average yields for the varieties of *T. durum* grown at each station and for similar periods. For comparative purposes the 7-year period S. E. and N. W. have here been selected.

The Kubanka gave 24.7 bus. per acre (S. E.) and 28.6 bus. (N. W.). Arnautka, 20.2 bus. (S. E.) and 28.8 (N. W.). The Monad and Acme have not been grown as long. The data available for them, however, in comparison with the other varieties, are interesting and conclusive, e. g. at Fargo (S. E.) in 4 years, Monad gave a superior yield to Kubanka by 3.5 bus. per acre and at Williston (N. W.) after 3 years the superior yield amounted to 3.6 bus.

In 1913, 13 % of the wheat acreage in N. Dakota was cropped with durum wheat and in 1920 this rose to 36 %; it is estimated that in 1921, about 45 % of the acreage will be devoted to durum.

*Stem rust infection.* — Comparative estimates are given in tabular form of the percentage stem rust infection for the principal varieties named and these indicate that of the common wheats Marquis, although not resistant, being an early wheat other things being equal, is thereby helped to escape rust attack to a large extent. Other varieties such as Power, Haynes and Preston are very susceptible to rust, but the Kota var. (Preston group) appeared to be comparatively resistant. The durum wheats are apparently, taken as a whole, more resistant both to rust and also to drought. Monad and Acme show up well in this respect and D. 5 was the least susceptible of any of the varieties named.

Observations relative to the susceptibility of varieties have been made at Fargo and Dickinson over a series of years. Taking first the S. E. section for a 7-year period, the average percentage of infection is estimated as follows: (Common) Power 49.7 to 58.4, Marquis 38.3, Dakota 49.0, Preston 47.1. (Durum) Kubanka 30.1, Arnautka 34.7, Kahla 23.7, Gharinovka 26.3. For a 3-year period Nomad showed only 1.3 % infection and Acme 2.0 %; taking next the S. W. section, a 3-years average gave: (Common) Power 24.1, Red Fife 22.8, Marquis 23.2, Haynes 24.6, Preston 29.0, Pioneer 17.6; (Durum): Kubanka 10.7, Kubanka No. 8, 12.5.

Full details are given in the tables of the infection percentage for each individual year.

**MATURITY REQUIREMENTS.** — On an average for 7 years (1913-20), at Fargo (S. E.), Marquis matured in 87.8 days, Preston 88.5, Power 91, Dakota 92.5, and Kubanka 91.7. Other data are also given.

**HEIGHT OF PLANTS.** — There did not appear to be much variation in height. Taking the 2-year period (1918-20) as an example, in the Fife group, the height ranged from 37 inches Power, to 40.5 Kitchener, in the Bluestem the range was from 38.5 to 40.5, in Preston, 39.5, and for the Amber durums, 41.0 to 41.4 in. Full details are given in tabular form comparing some agronomic characters for established and promising new varieties of wheat in the S. E. and S. W. areas.

**STRAW YIELDS.** — Durum wheats in general produce longer, and thus

more straw than the common wheats. At Fargo, Kubanka has yielded more straw on an average than any of the other established varieties. Marquis did not produce as much straw as Power or Dakota, but more than Preston. All straw yields were less in the S. W. section than in the S. E., this was especially noticeable in the case of Marquis which gave exceptionally light yields. However, the low rainfall in the S. W. area has frequently been a big factor in preventing the normal development of plants. Taking the yields as a whole, with the common wheats, the Fife group gave on an average for a 6-year period, 3475 lb. (Marquis) to 3734 lb. (Power): Bluestem group, 3596 to 3974 lb; Preston 3304 lb. and with the durum wheats, 3747 and 3748 lb. for Kubanka and Arnautka respectively.

Tables are given of data with regard to the yields per acre for the various years.

**WEIGHT PER BUSHEL.** — It does not necessarily follow that a high bushel weight alone, means a high quality of wheat, or wheat of high milling and baking value. According to the appended table, the average weight per bus. in lb. varies from 51.5 to 56.9 lb. for the Fife, Bluestem and Preston groups, and amounts to 59.4 lb. for var. Prelude. For the durum wheats, the average weight is evidently higher and varies from 59.3 to 61 lb. (In both the above-mentioned cases the data here refer to the S. W. Section and a 1-year period).

**MILLING AND BAKING QUALITIES.** — In this connection observations have been made at Fargo (S. E.) since 1917 and at Dickinson (S. W.) since 1911. The data given in the present publication include the comparative yearly percentage of straight flour from the principal varieties; the amount of water the flour absorbs, or requires, to make dough of proper consistency; the volume of the loaf baked from the flour, and averages showing the rating as regards colour and texture of the loaves. Flour from Marquis is apparently superior to that from other commercial varieties for bread-making purposes. Durum wheat flour does not appear to have the strength of gluten associated with flour from common wheats. Of the commercial amber-durum varieties, Kubanka is superior to Arnautka. Monad, a variety of more recent origin, and Acme are distinctly superior to Kubanka as regards yield but its flour gives a smaller loaf. The D-5, red durum, yields well; its milling and baking qualities are, however, distinctly of inferior quality, and do not satisfy the requirements of either the bread or macaroni trade.

160 - **The Composition of Wheat Affected by Meteorological Conditions** — SHUTT, E. T. (Chemist for the Dominion of Canada), Report of the Chemist, in *Rapport des Fermes Expérimentales du Dominion*, Fiscal Year ending March 31, 1920, p. 59. Ottawa 1921.

This study which was begun in 1908, shows that climatic and seasonal conditions not only affect the wheat yield, but may also exert a powerful influence upon the protein content of the grain. Wheat from the same parent stock was sown at the various experiment farm and Stations, and careful observations and records were made of the crops obtained, and the temperature during the growth period. One sample of wheat from each

plot is analysed, and the data are incorporated in the form of tables, in the meteorological statistics.

On account of the War the analysis of the wheat samples had been interrupted since 1916, but has now been resumed and the results will be correlated with the temperature statistics, in order to see the influence of environment upon growth, composition and yield. The first results obtained by this method of research have shown that the conditions favourable to the formation of the hard kernel, rich in gluten, characterising wheat of good quality, are a relatively dry soil, and the prevalence of a relatively high temperature during the time that the grain is filling out and ripening.

161 - **Satisfactory Results obtained in Italy with a Variety of Rice from the United States.** — NOVELLI, N., in *Giornale di Riscoltura*, Vol. XI, No. 12, p. 181-183. Vercelli, December, 1921.

The "R. Stazione sperimentale di Riscoltura" of Vercelli has imported from the United States 2 varieties of rice called American 1561 and American 1600. As the grain of both is good and the varieties were said to be very productive, trial crops were grown not only at the Station itself but on several agricultural farms and by many competent farmers in various parts of Piedmont, Lombardy and Emilia.

American 1561 never ripened; while American 1600 proved similar in development and vegetative growth to the Italian variety "originario," although perhaps it produces less straw. Average height 1.45 m.; tillering average; 15-18 culms; a little more resistant to lodging than "originario" owing to its rather slender flexible stem with many vascular bundles, and its more compact panicle; ripens at the same date as "originario," or perhaps a little earlier; ears denser with an average length of 20 cm., each bearing 160-180 kernels; production generally good, being about 60 quintals of paddy per hectare (one agriculturist obtained over 70 quintals); grain similar to that of "originario," glumes very thin and lighter in colour. This variety does best on slightly clayey soil.

The author is of opinion that it is worth breeding, and the seed section of the Vercelli "Stazione di Riscoltura" has already taken the work in hand.

162 - **Gembok Beans (*Bauhinia Esculenta*) from South Africa.** — *Bulletin of the Imperial Institute*, Vol. XIX, No. 2, pp. 142-144. London, 1921.

The seeds of the leguminous plant *Bauhinia esculenta* have been examined recently at the Imperial Institute, at the request of the Chief Division of Botany, Union of South Africa. It was stated that the seeds, which are known locally as "Gembok beans" are utilised in the South-West Protectorate both for native consumption and for feeding animals, and it was desired to ascertain their precise food value and whether they contain any injurious substance.

The seeds were dark reddish-brown in colour, about  $\frac{1}{2}$  to  $\frac{5}{8}$  inches

in diameter, with woody shells, 49 %, and oily kernels 51 %, cream-coloured with a pleasant, nutty but slightly bitter flavour.

The kernels contained 4 % of moisture ; on extraction with ether the yield was 41.6 % of a golden-yellow limpid oil, equivalent to 43.3 % from moisture free kernels.

The appended Table shows the composition of the kernels, shells, entire seeds, residual meal (containing 7 % fat) compared with that of decorticated cotton-seed cake.

	<i>Bauhinia esculenta</i>				Decorticated cotton-seed cake
	Kernels	Shells	Entire seeds	Meal	
Moisture . . . . .	4.0 %	8.5 %	6.2 %	6.4 %	8.65 %
Crude protein . . . . .	32.8	2.5	18.0	52.2	40.25
Fat . . . . .	41.6	0.2	21.3	7.0	7.93
Carbohydrates (by difference). . . . .	17.2	67.2	41.6	27.4	26.06
Crude fibre . . . . .	1.3	19.8	10.4	2.1	10.16
Ash . . . . .	3.1	1.8	2.5	4.9	6.95
Nutrient ratio. . . . .	1 : 3.4	1 : 27.1	1 : 5.0	1 : 08.3	1 : 1.1
Food units . . . . .	203	74	140	175	147

The oil extracted, which has a pleasant odour and taste, possessed the following characteristics, compared with cotton seed oil (given in brackets) :—

Specific gravity 0.9211 (0.922-0.925) ; refractive index at 40° C, 1.464 ; solidifying point of fatty acids, 30.6° C (35°-38°) ; acid value 0.6 ; saponification value 190.0 (192-195) ; iodine value 95.6 % (105-115 %) ; unsaponifiable matter 0.8 % (0.8-1.8 %), volatile acids, soluble 0.3 ; insoluble 0.1.

The results show that the kernels of *B. esculenta* are rich in protein and oil, and that the oil resembles cotton-seed oil. The meal contains a high percentage of protein but a poor fibre content, and in these respects is superior to decorticated cotton-seed cake.

No injurious substance was found in the seeds, but it has not been definitely established that they are harmless : it is considered advisable therefore to carry out feeding trials before definitely recommending the beans for general use as a feed. For this purpose, the hard shells should be removed, as they are woody and of low food value.

Up to the present no information appears to be available regarding the composition of *Gembok* seeds and their use as a feeding stuff, but the seeds of certain species of *Bauhinia* are stated to be employed as a feed in India.

If available in sufficient quantities, these seeds seem likely to be of distinct value both as foodstuffs and for oil extraction.

163 - **Development of Potato Tubers. Experiments Made in Colorado, U. S. A.** — CLARK, C. F. (Office of Horticultural and Pomological Investigations) in *Bulletin No. 958, United States Department of Agriculture*, pp. 1-27, figs. 10, tables 11, Bibliography of 12 works. Washington, D. C., Aug. 22, 1921.

The experiments here described were carried out at the Colorado Potato Experiment Station, Greeley, during the seasons 1916-18. A few minor observations were also made in Maine in 1919 for the purpose of verifying previous conclusions as to the time of the beginning of tuber formation. While these studies could profitably be extended to cover a longer period and include a greater number of varieties and a wider range of environmental conditions, the author considers it advisable to place on record the results obtained up the present time.

The material used for the experimental work was grown under field conditions, the cultural operations following those in general use in the locality. The minimum size of tuber saved was  $\frac{1}{2}$  inch. When a separation was made into marketable potatoes and culls, the division was by weight, the former including those equal to or exceeding 3 ounces and the culls those below this limit.

The statistical studies of tubers at one-week intervals showed that the greater part of those which grew to exceed  $\frac{1}{2}$  inch in diameter were formed at the start of tuber development. The maximum rate of growth of tubers was found to occur at the end of August or beginning of September, approximately 80 days after planting. At this time nearly  $\frac{1}{3}$  of the total period of tuber development had been completed. The differences in the sizes of the tubers in the individual hills may be attributed largely to the unequal rate of growth rather than to the differences in the age of the tubers. A small increase in the weight of tubers was found to occur after the vines had been killed by frost.

The weight of the tuber did not appear to be correlated with the length of the stolon upon which it is produced. The average data show a tendency towards a decrease in the size of the tuber on the upper stolons, though the individual plants showed considerable diversity in this respect. The greatest average weight was produced by the lowest stolons in the 2-stolon and 3-stolon groups; while in the 4-stolon group the maximum production was in the second position, with a gradual decrease in the weight in the upper stolons. Larger numbers of observations are however needed to establish the laws governing these relationships.

The number and weights of tubers per hill were found to be influenced by the size and kind of sett planted. The relative influence of whole and cut setts on tuber production using the Rural New Yorker variety of potatoes has been determined and it appears, according to the data given that a slightly larger number and with one exception a larger weight of tubers per stem was obtained when whole setts were used.

The fact that the tuber producing ability of different varieties varies considerably with respect to the number and weight of tubers per hills is brought out very clearly in the diagrams showing the number and weight of tubers per hill produced in 500 hills of Rural New Yorker (average

4.5 and 860.7 gm. respectively) and 500 hills of Pearl (average 6.9 and 944 gm. respectively). A further comparison of the behaviour of different varieties under varying treatment with respect to irrigation was made. (The varieties tested were Triumph, Early Ohio, Charles Downing, Russet, Burbank, Peachblow, Late Ohio, in addition to the two varieties above mentioned. The number of tubers per hill ranged from 3.8 in Rural New Yorker to 7.1 Charles Downing. The lowest average weights per hill were produced by the two early varieties, Triumph and Early Ohio, the highest by the late variety, Pearl. Apparently the application of water before tuber formation had begun, increased the number of tubers. Increasing the number of irrigations appears to have had little effect on the number of tubers; the weight per hill was however increased by each additional irrigation except where the applications were too frequent.

The experiments on different types of soil revealed the existence of a close relationship between the character of the soil and the number and weight of tubers. Fine sandy loams invariably gave the best results, the number of tubers per hill (Rural New Yorker var.) being 6.3 and weight of tubers per hill 1033.5 gm. (average 162.8) compared with clay loam, 4.9, 663.7 gm. (average 136.5) and heavy clay 3.0, 376.7 gm. (average 125.3) respectively.

FORAGE  
PLANTS

164 - **The Barajillo (*Meibomia Rensoni*), a Good Leguminous Forage Plant, Indigenous in Central America** (1). — RENSON, C., in *Revista de Agricultura Tropical, Órgano de la Dirección general de Agricultura e Industria, República de El Salvador*, Vol. I, No. 2, pp. 65-71, 8 figs. San Salvador, February 1, 1921.

The barajillo, which is also called "Juana larga", "vara de arco", "arquillo", etc., is a Leguminosa belonging to the group of the Hedysareae. It has been identified by PAYNTER (of the Bureau of Plant Industry of the United States Department of Agriculture), as *Meibomia Rensoni* n. sp., and grows wild in Central America at altitudes of between 600 and 1200 m. in places that are not frequented by livestock, for horses, mules and cattle eat it with such avidity that they end in entirely destroying the plant. When left undisturbed and allowed to grow freely, *Meibomia Rensoni* forms a small tree 5 to 6 metres in height, with slender, unbranched trunk terminating in a heavy bushy crown which makes the stem bend in a bow.

The fruit is a lomentum that easily breaks across at the joints; the latter are hard and contain a single seed.

If these pieces of the lomentum are planted in ploughed land, the seeds do not germinate; this fact has been stated by many agriculturists, and was proved by the author's experiments. The small seeds must be removed from the pod without injury and, according to the author, this is best done by placing the seeds on a plate of rubber and running

(1) For *Desmodium leiocarpum* G. Don (= *Meibomia leiocarpa* = *Hedysarum l. iocarpum* Spreng = *Hedysarum erectum* Vell) as a forage plant in Cuba, see R. December, 1920, No. 1097. (Ed)

a rubber-roller over them. After the ground is ploughed, it should be harrowed and rolled; the seeds (mixed with soil) must be sown broadcast and not covered with earth. They germinate in about 12 days, and the plants grow so rapidly that in 5 months their height exceeds that of a man.

The author advises a wide growth of this excellent forage plant in Central America, for the only artificial meadows in that country are "zacatales" composed of Graminae, and the need of a forage leguminosa is all the more keenly felt, because only negative results have been obtained with the foreign species hitherto tested.

165 - **Florida Beggar Weed (*Desmodium Tortuosum*)** (1). — MUNDY, H. G., in *The Rhodesia Agricultural Journal*, Vol. XVIII, No. 3, pp. 504-505, pl. 1. Salisbury, October 1921.

For many years, Florida beggar weed (*Desmodium tortuosum*) has given excellent results on the Experiment Station at Salisbury with or without irrigation, and without any special soil treatment. During the season 1920-21 one plot of beggar weed sown in January 1920, was cut as follows:

1st cutting (Oct. 6), height 12 inches, 2nd cutting (Nov. 20), height 18 inches, 3rd cutting (Dec. 30), height 21 inches, 4th cutting (Feb. 16), height 21 inches, 5th cutting (March 20), height 18 inches, 6th cutting (June 8), height 9 inches.

Growth on the earliest cutting was hastened by irrigation (one watering in September). A second watering was given on October 10, after which the crop was entirely dependent upon rainfall. The 6th cutting yielded 1170 lb. of green fodder per acre, and since this was the shortest growth of any, it may be safely assumed that the total yield of green forage per acre for the 6 cuttings was not less than 12 000 lb.

Further reports from other districts of Rhodesia bear out the opinion already formed of this crop.

The stalks of *D. tortuosum*, as they mature, become hard and woody and it is therefore recommended to cut or graze frequently and before it becomes too mature. The seed germinated easily, and is extremely hardy when young, very few plants burning or wilting even during drought.

Although this crop cannot be reckoned as equal in quality, where lucerne cannot be grown without great difficulty, beggar weed has been shown to be the next best substitute.

166 - **Method for calculating the Production of Pastures.** — See No. 183 of this Review.

167 - **Piedmont Hemp.** — DOLCI, E., in *La France et le Marché italien, Organe de la Chambre de Commerce Italienne à Paris*, Year XXXVI, Nos. 245-247, pp. 291-293, figs. 2. Paris, July-September 1921.

Report of Prof. Ermanno DOLCI, Technical Delegate for the Industrial and Agricultural Development of Piedmont hemp.

(1) For nitrogen content of *D. tortuosum*, See R. Dec. 1917, No. 1126. (*Fd.*)

Italian hemp has long been imported into France, and the quotations of the Bologna and Naples hemp markets are given on the Stock Exchanges of Paris and Marseilles. The author does not speak of the classic varieties of Campania and Emilia but deals solely with Piedmont hemp (*Cannabis sativa* var. *excelsior*).

The seed of this variety has for many years been imported from Carmagnola into the hemp-growing regions of Anjou and Touraine, especially into the district between Saumur and Daguemère. The seeds are sown very far apart and produce large branched plants from which the fibre known as "fils du Piémont" is obtained. This variety is sown in the fields where rope-making hemp is cultivated, and its fibre is called "petit-fils du Piémont." It is this selected seed that is bought by the growers of Basse-Loire and provides the hems for spinning, known as "chanvres pour filature".

It may be said that the Piedmont hemp seed has now acquired a world-wide reputation. Its biological characters are well-known and have been the subject of careful experiment in France, Serbia, Russia and America owing to a great extent to the initiative of the "Cassa Rurale di Villanova Solaro" (Cuneo), which has its Head Office at 22 Via Balbo, Turin.

Some large French string-factories (for instance that at Mâcon) prefer the Piedmont tow to the classical product of Emilia, and also to the Neapolitan variety, for though less pliable it is not at all woody on account of the special hand-treatment it receives. The worker seizes the base of the stalk to be decorticated, removes the cortex covering the root, and breaking the stalk into two or three pieces, then detaches it from the tow, that is to say, the stalk is removed by hand from the tow, and not the tow from the stalk. The stems are from 4 to 5 metres long and their circumference at the base varies from 3 to 5 cm.; further the amount cultivated by each grower is small (for the land is much subdivided), so the work is not so laborious as would at first sight appear; for which reason, no attempt has been made to substitute more rapid mechanical work for this manual labour. The tow after being made into hanks, is sold on the markets of Carmagnola, Vigone, Carignano and Pignerola. The hemp is known by a number of new technical names. The type called "buona" at Bologna, "macerata in tiglio" at Rovigo, and "extra," in Naples is sold in Piedmont under the title of "naturale". The fibre of stalks that have been cut by hail or are insufficiently developed is called "molletto", while the product of female plants that have borne fruit, and the tow of stalks retted by the dew, pass respectively under the names of "meschiasso" and "antersecco."

During the season an average of nearly 70 tons of first quality tow is sold weekly at the above-mentioned markets. It is always sold uncombed, for the combed hemp is all taken up by a hundred domestic-rural rope factories at Carmagnola.

100 kg. of raw tow yield: 37.75 extra tow; 35 kg. ordinary tow — 16.25 kg. of residuum (roots, oakum); 11 kg. of heterogenous substances (dust).

The 16.25 kg. of residuum furnish an excellent textile fibre that can be used in rope-making. The only really waste product is the dust; this comes from the soil adhering to the roots (in Piedmont the hemp is not cut, but pulled up), or found in the retting water. The sole defects of Piedmontese hemp are its want of flexibility and the coarseness of the fibre which limit its use in rope-making.

In order to obtain a fine flexible fibre, it is only necessary however to sow the hemp more thickly instead of planting 40 to 50 seeds per square metre, or at the rate of 30 to 50 litres per hectare (300 litres per hectare in France) according to the present custom. On the other hand, broad casting has the advantage of producing much larger seeds which are greatly appreciated and are even more profitable than the tow. In 1920, they fetched 708 *lire* per quintal. The result of sowing this hemp in the Loire valley was to increase the production by about 30 %. The characters that have made it celebrated are: resistance to bad weather, immunity to certain plant parasites and luxuriant growth.

The industrial treatment of the fibre is still based on antiquated methods and a large wooden wheel turned by hand is employed. The "Cassa Rurale" of Villanova Solaro is setting up modern plants.

The conditions at Carmagnola are most suitable for a hemp-factory, for the supply of electric power is plentiful and there are abundant means of communication with the sea through Genoa, and the interior and foreign countries, via Modane and the Simplon.

168 - *The Agave and Fourcroya gigantea at Tran-Ninh Indo-China.* — MIEVILLE M. R. (Chef de la Station agricole du Tran-Ninh), in *Bulletin agricole de l'Institut Scientifique, de Saigon*, Year 3, No. 11, pp. 360-364. Saigon, November, 1921.

AGAVE. — Description of the distribution, development of the plant and extraction of fibre with reference to plants under observation at Tran-Ninh.

The leaves of 1.50 m. length weigh on an average 2.35 kg., and 90 gm. of dry fibre are obtained, i. e. a yield of 3.83%. If the fibre proves to be of superior quality there appears to be no reason why the method of extracting fibre should not be facilitated and the industry extended. The country round Tran-Ninh is peculiarly adapted to the cultivation of the agave.

*Fourcroya gigantea.* — Bulbs were imported into Indo-China from France in 1911 and proved very adaptable to the new climatic conditions etc. The first collection of leaves was made in 1919, and it was found that 100 kg. of leaves gave 2.186 kg. of washed and well dried fibre. The fibre was larger than that obtained from agave, and was very white and shining. Air drying or sun drying has been found equally effective and the process is rapid, only requiring a few hours. The "Monodéfibreuse" fibre machine is recommended owing to easy transport, etc. A new plantation was made in 1921 on a steep slope and is so far progressing satisfactorily. *F. gigantea*, can be planted with success under trees with fallen leaves. Fine specimens have also been noticed growing in thickets. at Tran-Ninh. Drought appears to have no ill effect.

Details are given of propagation, planting, arrangement of plantation (spacing, etc.), cultural operations, defibration, etc.

169 - **Giant Grasses for Paper-Making (1) in India, Africa, Australia and the West Indies.** — In *Bulletin of the Imperial Institute*, Vol. XIX, No. 2, pp. 174-189 and Vol. XIX, No. 3, pp. 271-282. London, 1921.

A summary of work already done in connection with the utilisation of several species of wild large stemmed grasses, exclusive of bamboos. Apart from the giant forms, reference is also made to certain smaller grasses when these occur in association with the giant kinds or might be employed in paper-making in conjunction with them.

INDIA. — *Ischaemum angustifolium* Hackel (= *Andropogon involutus*, Stendel) the "sabai", "baib" or "bhabar" grass of Northern and Central India. This grows to a height of 6-7 ft., and gives two abundant crops a year without irrigation. It yields 40 % or more of cellulose. According to RAITT it is one of the best and cleanest materials known for the production of the finest printing and medium quality writing paper; even the nodes do not offer any serious resistance to the action of reagents.

*Themeda gigantea*, Hackel, sub spp. *arundinacea* and *villosa*, "ulla-grasses". The larger form is most abundant in N. W. India, growing to a height of 17 ft., and estimated to yield 3.5 tons per acre per annum if cut on a 3-years rotation. RAITT gave its composition as over 50 % cellulose, 28 % pectose etc., nearly 15 % water solubles and over 6 % lignin; average length of ultimate fibres as 2.87 to 2.9 mm., classing it first among Indian savannah grasses. When tested on a commercial scale both in India and in England, it was found difficult to bleach and hardly answered expectation but it could no doubt be used advantageously for admixture.

*Phragmites Karka*, Trinius (= *P. Roxburghii*, Kunth) "nal". This grows from 9-14 ft. high, its yield being estimated by HOLE at 3.2 tons per acre per annum on a 2-years rotation. Composition is nearly 48 % cellulose, 33 % pectose, etc. 12 % water soluble and 7 % lignin, its ultimate fibres averaging 2 mm. in length; yield 39 % unbleached pulp. It is considered a first class paper-making grass.

*Saccharum* spp. — *S. arundinaceum*, Retz, apparently including *S. procerum* and *S. exaltatum* Roxburgh, is a widely distributed gregarious species, occurring throughout India up to altitudes of 4,000 ft. It takes 3-4 years to reach maturity, and should therefore be cut on a 4 to 5 years rotation. It grows 18 to 23 ft. in height and gives a yield of 14.8 tons of dry material per acre per annum; the yield is stated to be best at the flowering season. The percentage of bleached fibre from the entire plant is stated to be 36.5, the composition of the plant being 52.9 % cellulose, 9.1 % lignin, 27.5 % pectose etc. and 10.5 % water soluble matter. This is classed among the best of the Indian savannah grasses whether for use

(1) For Plants used for Paper-Making and the Utilisation of Bamboo-, See R. May 1921, No 498. (Fd.)

by itself or for admixture and its yield per acre is more than twice the amount of any other species.

*S. ciliare* Anderss. (including *S. Munja* and *S. Sara*, Roxburgh). This grows to a height of 17 ft. and under a three years rotation will give 5.6 tons of material per acre per annum and yields 40 % bleached fibre. Composition of entire plant 51.4 % cellulose, 32.6 % pectose etc., 10.7 % water soluble matter, 5.3 % lignin. The nodes are very slightly lignified and the pulp bleaches well, resembling that obtained from wheat straw.

*S. Narenga* Wallich. Occurs in the sal forests from the Sub-Himalayas to Burma, grows 18 ft. high and gives 3.5 tons per acre per annum on a 3-years rotation. It contains 48 % cellulose, 33.9 % pectose, etc., 11.3 % water soluble matter, 6.8 % lignin. It is considered of equal value to *S. ciliare*, *S. arundinaceum*, and *S. spontaneum*.

*S. spontaneum*. — Widely distributed and gregarious species, occupying thousands of acres in Assam and reaching altitudes of 6000 ft. in the Himalayas. It has vigorous underground growth and sends up culms 7-14 ft. high. Yield 7.8 tons of air-dry material per acre, or 2.9 tons per annum on a 2-years rotation; ultimate fibre 0.8 to 2.8 mm. in length; content 45.8 % cellulose, 36.2 % pectose, etc., 9.4 % water soluble material, 8.6 % lignin. The stems are apparently very satisfactory as pulp material, but the leafy heads do not bleach well. The species occupies flooded or moist areas and occurs also in S. China and in the Caroline Islands.

*S. fuscum* Roxburgh (= *Miscanthus fuscus*, Benth) 5-9 ft. high requiring a 2-years rotation; a native of moist ground in Assam, Bengal and Burma; estimated to give 2.3 tons per acre per annum, but classed by RAITT as somewhat inferior in strength.

*Erianthus Ravennae* Beauvais (= *Saccharum Ravennae* L.) "Pampas grass". Grows 17 ft. in height and is estimated to yield over 7 tons per acre but should be cut on a 3-years rotation; fitted only for use in admixture.

*Imperata arundinacea* Cyrill (1) (including *I. cylindrica* and *I. Koenigii* "lalang." Reaches altitudes of 7000 ft.; has a creeping rhizome with erect solid culms 1.3 ft. high. Var. *latifolia* 3-4 ft. high with broader leaves found in the warmer parts of the Himalayas. Under a 2-years rotation could yield 1.7 tons dry grass per acre per annum. It is used at the present time in conjunction with bamboo etc. in paper mills in Indo-China and Queensland (2) and has proved successful in the Federated Malay States.

*I. exaltata* Brongniart, grows gregariously and is resistant to drought, ultimate fibres 0.46-1.82 mm. in length; for cheaper printing papers, but poor in colour.

*Arundo Donax* L. "Spanish reed." Widely distributed in warm and wet districts grows from 5-16 ft. in height; estimated to yield over 3

(1) See R. Feb. 1917, No. 149, and R. May 1921 No. 498. (Ed.)

(2) See R. Nov. 1916, No. 1162, and R. May 1921, No. 498. (Ed.)

tons per acre per annum on a 2-years rotation. Composition nearly 43 % cellulose, 33 ½ % pectose, etc., 14 % water soluble matter and over 9 % lignin. Ultimate fibres average 1.5 mm. length. Paper produced is of fairly good quality and the plant is placed in the first class of Indian savannah grasses by RAITT and HOLE.

*Andropogon intermedius* R. Brown. (Referred to by STAFF as *Amphiphis*). Widely distributed up to 8 000 ft. in India, N. Australia, Tropical Africa and W. Indies. Grows 7 ft. high; yields about 4 tons per acre or 2 tons on a 2-years rotation; classed as 2nd class paper making material.

*Heteropogon contortus* ("spear grass") Roem and Schults (= *Andropogon contortus* L.) widely distributed throughout the plains up to 5 000 ft.; grows 3-4 ft. high and estimated to yield 1 ton per acre on a 2-years rotation. When tested by RAITT it proved too refractory to serve as a pulp-material even in admixture form.

*Pennisetum Alopecurus* ("Moya grass") Stendel. From 15 000 to 20 000 tons available annually in neighbourhood of Pench Valley, coal-field in Central Provinces; said to yield 39 % of easily bleachable pulp.

*Eragrostis cynosuroides*, Roem and Schults, "dab" grows on barren sand in N. India. Perennial growing, 5ft. in height; estimated by HOLE to yield 1 ton per acre per annum on 2-years rotation; ultimate fibres average only 0.94 mm. in length and the pulp proved weak and difficult to bleach. It is considered therefore suitable only for admixture with superior grass pulp in a proportion not exceeding 10 %.

SOUTH AFRICA. — Tambookie Grasses (1). — Reference is made to *Cymbopogon validus* Stapf (= *C. Nardus* Rendle var. *validus* = *C. marginatus* var. *validus* Stapf). *C. excavatus* Stapf (= *Andropogon Schoenanthus* L. var. *versicolor* Hackel), *C. hirtus* Stapf (= *Hyparrhenia hirta*), *C. auctus* Stapf, *C. Ruprechtii* Rendle (= *Hyparrhenia Ruprechtii* Fourn.), *Andropogon cerasiaeformis* Nees (= *Monocymbium cerasiiforme* Stapf), *A. Dregianus* (= *Hyparrhenia Dregiana* Stapf.) and *Erianthus Sorghum* Nees.

*Andropogon Buchanii* Stapf. "dek" or thatching grass has also been tested at the Imperial Institute (1).

*Trachypogon plumosus* "stek grass" Nees. — Comprises most of the forms included under *T. polymorphus* Hackel and under this name a sample was reported on by the Imperial Institute (2).

*Themeda triandra* Forsk (including African forms of *T. Forskalii* Hackel (1), *Anthistiria imberbis* Retz and *A. ciliata* Nees). Examination proved that the ultimate fibres are mostly 1.5 to 2.0 mm. long, and yield about the same quantity and quality of pulp as the "tambookie" and "dek" grasses; the nodes are, however, harder and would necessitate thorough boiling and beating.

(1) See R. Feb. 1920, No. 202. (Ed.)

(2) See R. May 1921, No. 498. (Ed.)

*Sorghum halepense* "Johnson grass".

*Andropogon hirtiflorus* Hootefel. var. *semiberbis* Stapf. (= *Schizachyrium semiberbe* Nees (1)).

*Tristachya Rehmanni* Hackel (1).

*Aristida* sp. gave pulp inferior to ordinary chemical wood pulp, but would be only profitably manufactured for local use (*Union S. Africa Industries Bull.* No. 7, 1919, p. 66).

*Panicum obscurans* Stapf, also known as *Isachne obscurans* Woodrow (1).

WEST AFRICA. — Ten different species have quite recently been received from Nigeria for a test of their suitability for paper manufacture.

1) *Imperata cylindrica* Beauv. "ekong". Chemical examination gave moisture 10.1 %; cellulose 41.3 %, ash 5.2 %. The ultimate fibres measured from 0.6 to 1.3 mm. Tests proved that the refractory part of the material consists of the hard rhizomes and that, if care is taken to exclude these in collecting the grass, a fair yield of pulp of good quality will be obtainable.

2) *Pennisetum* sp. "esun". Composition:— moisture 10.1 %, cellulose 41.6 %, ash 7.3 %.

Under drastic conditions with caustic soda, the grass furnished a pulp which broke up fairly well, bleached to a fairly satisfactory cream colour and felted well, giving a good strength of paper. The yield was however rather low.

3) *Andropogon tectorum* Schum. Composition:— moisture 10.8 %, cellulose 44.2 %, ash 4.2 %. The pulp bleached well to a pale cream colour and yielded a paper of fairly good strength.

4 and 5) *Andropogon Gayanus* Kunth. Two specimens "jinfi" and "gamba" both identified at Kew as *A. Gayanus*: "Jinfi" contained moisture 8.9 %, cellulose 50.9 %, ash 4.0 % and "gamba" moisture 8.8 %, cellulose 49.3 %, ash 3.8 %. Both gave a well disintegrated pulp giving strong good quality paper; less caustic soda was required for "jinfi".

6) *Chasmopodium Afzelii* Stapf, vel sp. nov. "sasari". Composition, moisture 8.8 %, cellulose 44.6 %, ash 6.1 %; somewhat drastic treatment with caustic soda was found necessary and resulted in a pulp with excellent felting powers giving a good white paper.

7) *Cymbopogon giganteus* Chiov. "tsauri". Composition moisture 9.1 %, cellulose 50.0 %, ash, 5.0 %. Very drastic treatment necessary; when the temperature was increased to 160° C, a satisfactory result was obtained and a paper of good strength.

8) *Hyparrhenia rufa* Stapf. "Yama". Composition: moisture 9.3 %, cellulose 40.9 %, ash 7.6 %; drastic treatment required resulting in a well disintegrated pulp of good quality and strength.

(1) See *R. Feb.* 1920, No. 202; *R. May* 1921, No. 498. (*Ed.*)

*H. rufo* Stapf. "Kitsi gujma", moisture 8.9 %; cellulose 42.0 %, ash 6.3 %; results similar to first species but requiring less drastic treatment the sample being rather thinner and less mature.

9) Mixture of *Andropogon Gayanus* Kunth, *Hypparrhenia subplumosa* Stapf. and *Trichopteryx* sp. "baya Maria". Composition: moisture 9.2 %, cellulose 40 %; ash 5.0 %. The pulp did not break up sufficiently at first beating, but after bleaching and further treatment gave a strong opaque paper of satisfactory quality and colour.

10) *Ctenium elegans* Kunth, "wuchiyan bera". Composition: moisture 8.3 %, cellulose 47.6 %, ash 3.1 %. Requiring at least a 20 % caustic soda treatment to give a pulp which after bleaching broke up well and gave a strong white paper.

EAST AND CENTRAL AFRICA. — *Pennisetum purpureum*, Schumacher (= *P. Benthamii* Stendel). "Elephant Grass" culms reach 6.10, or 20 ft. in height — in smaller form grows at an altitude of 5 000-6 000 ft. — very abundant. It has been calculated that 2 crops could be cut annually, yielding 60 tons dried grass per acre, from which 25 tons of pulp could be obtained. The favourable results obtained on a laboratory scale have been confirmed by a large-scale trial conducted at a paper mill in the United Kingdom, and the material has since been used for Government printing paper in Uganda and appears quite satisfactory.

AUSTRALIA. — *Imperata arundinacea* (See India). It may be added that it has been employed for pulping on a small scale at Cairns, Queensland (Bulletin No. 11, 1919, Commonwealth Advisory Council of Science and Industry). Its utilisation for paper-making is not considered as likely to be profitable.

*Triodia irritans* R. Brown. Tested but found unsuitable (See Bull. mentioned above).

*Spartina cynosuroides* Roth (= *S. Schreberi* J. F. Gmelin), recommended for cultivation as a paper material in Victoria. It is a native of freshwater swamps in eastern N. America.

WEST INDIES. — *Panicum molle* Schwartz (= *P. barbinode* Trinius). "Para grass". This has been employed to advantage in Trinidad in conjunction with bagasse and bamboo. It has been previously estimated by CARMODY that 30 000 tons of bagasse-pulp, worth £12 per ton, available annually in Trinidad, would be increased in value to £15 per ton by the admixture of bamboo and para grass.

*P. myuros* "camelote". Strong, but pulp only suitable for wrapping paper.

*Uniola racemiflora* Trinius (= *U. virgata* Grisebach). Stated to be useful for paper pulp although inferior to esparto.

CONCLUSIONS. — Except in the case of the Indian Savannah grasses, it has yet to be definitely ascertained how far those giant grasses taken as a whole, could withstand repeated cropping, or on what rotation this would be possible. Careful local surveys would also be necessary to determine the existence of adequate and accessible supplies to meet the demands of the mills, etc. In every case where export is concerned, it is

necessary that the grass should be converted into "half-stuff" in the country of origin, as under present conditions, the raw material would not realise a sufficiently high price in Europe to justify the cost of transport.

- 170 - **The Oil-Bearing Sunflower on the "Riviera di Ponente", Italy.** — PERSICO, W. in *Costa Azzurra Floreale-Agricola*; reprinted in *Bollettino dell'Associazione Italiana pro Fianze medicinali, aromatiche ed altre utili*, Year IV, No. 10, pp. 155-156. Milan, October 1921.

PLANTS  
YIELDING OILS,  
DYES, TANNINS  
ETC.

The author recommends that the large, one-flowered, so-called Russian variety of *Helianthus annuus* should be grown as an oleiferous plant in the Riviera di Ponente, as its product is quite equal to olive-oil. Very satisfactory trials have been made in the experiment vineyards and rose-gardens of Pietralunga, where it has been found that about 20 quintals of seed per hectare may be expected. The seeds give 15 % of oil and 80 % of sunflower-seed cake, or 3 quintals of oil and 16 quintals of cake per hectare. Without irrigation, some plants, 46 cm. in height and with heads 46 cm. in diameter, were obtained.

The seeds of the sunflower are not only used for cakes, and in a variety of other well-known ways, but also supply an excellent flour for cake-making, while the stalks furnish a silk-like fibre and an ash with a high potash content. A brilliant yellow dye is obtained from the petals, and the leaves are used instead of those of *Datura Stramonium* as a remedy for asthma (1).

- 171 - **Gemsbok Beans (*Bauhinia esculenta*) as a Source of Oil.** — See No 162 of this Review.

- 172 - **Mangrove Species valuable as a Source of Tannin, in the Sunderbans, Forest Division of Bengal (India).** — DAS, B. M. (Superintendent, Calcutta Research Tannery), in *Journal of Indian Industries and Labour*, Vol. I, Pt. 1, pp. 482-490, Tables II, Bibliography of 16 works. Calcutta, Nov. 1921.

Although the species found in the various mangrove swamps of the world resemble one another the tannin content varies greatly in different regions, e. g. the bark of *Rhizophora mucronata* is reported to have on the average 20.5 % tannin in Borneo and 30 to 40 % in the Malay States. Hence the investigation of the mangroves in one region is no criterion of their economic value elsewhere. The Government of Bengal therefore deputed J. A. PILGRIM to make a systematic investigation of the tanstuffs of a promising area, namely the Sunderbans Forest

(1) For the use of the sunflower as a forage plant, see: R. April 1919, No. 193; R. Oct. 1920, No. 1008; R. March 1921, No. 289; R. Aug. 1921, No. 819; R. October, 1921, No. 1003.

Chopped sunflower stalks steamed for 3-4 hours make a good pig-food which the animals eat readily. As forage these stalks are superior to the straw of cereals: this is shown by the following analysis made at the Versuchsstation der Brandenburgischen Landwirtschafts-Kammer: Water 7.8 % — Crude protein 9.8 % — Crude fat 0.7 % — Nitrogen-free extracts 34.8 % — Crude fibre 33.8 % — Ash 13.1 % — M. KRAUSE in *Deutsche Landwirtschaftliche Presse*, Vol. XLIV, p. 684. Berlin, 1917. (Ed.)

Division on the South coast of Bengal. The main divisions of the work may be outlined thus :— *a*) general survey of the various species ; *b*) estimate of the species that predominate ; *c*) collection of the various parts of the trees with the object of ascertaining their tannin contents ; *d*) analysis ; *e*) deductions regarding suitability for the manufacture of tannin extracts or for direct use in tanneries ; *f*) small scale tanning tests with promising materials.

Reports were made on 18 varieties of which the following are the commonest in the Sunderbans :— 'sundri' (*Heritiera minor*), 'goran' (*Ceriops Roxburghiana*), 'gengra' (*Excoecaria agallocha*), 'keroa' (*Sonneratia apetala*). Good extracts can be made from several species, but the two first-mentioned, are the most common and abundant and their exploitation for this purpose may be regarded as of immediate commercial interest.

'Pussur' (*Carapa moluccensis*), a less abundant variety gave a valuable material ; extract made from the wood is expected to produce a tannage similar to that of quebracho extract which is largely used by tanners in Europe and America. Large scale tanning experiments with the above-mentioned promising materials are recommended.

The importance of careful collection and preservation of tanstuffs for their ultimate tannin content and colour has been proved. PILGRIM found the best method for preserving them in good condition was crushing and drying in the sun soon after collection from the leaves. The immediate crushing and drying kept the materials free from fermentation by expelling the moisture, and consequently preserving the tannin undeteriorated. In crushing, iron was as far as possible avoided and drying was done in the sun and in two cases only was artificial drying found necessary. In this way the formation of the unattractive reds through fermentation and oxidation in many tanning materials will be much reduced resulting ultimately in a better coloured tannage.

A striking illustration of badly preserved samples is given by the figures of analysis of some British East African mangroves. Well preserved samples of *Rhizophora mucronata* (1) gave 47.99 % of tannin and, badly preserved, 21.30 % only. Similarly, BLOCKEY reports some analyses of Indian mangrove barks and an interesting comparative percentage table is given for the BLOCKEY and PILGRIM analyses respectively : *Bruguiera gymnorhiza* (1) 9.7 and 31.55, *Kandella Rheedii*, 17.3 and 13.34, *R. mucronata*, 4.5-6.1 and 35.0.

In the present investigation, not only were bark, fruit, leaf and wood collected, but samples were also taken of the bark of twigs, branches and bole, of the outer husk and the inner kernel of the fruit, and of the young and mature leaves, of the branch and the bole wood.

Two main factors have been brought to bear upon the discussions regarding the suitability of the various materials analysed for extract man-

(1) See K. Sept. 1920. No. 871. (Ed.)

nufacture, namely: 1) the proportion of tannin to soluble non-tannin present in the material and; 2) the chloride content. Care was taken to calculate the yield of the extract in popular commercial forms, the expected percentages of tannin in the extracts and the quantity of material required to run an extract plant of suitable commercial size, *i. e.* with a daily capacity of 3 tons. Both in yield of extract and in percentage of tannin the following species stand out conspicuously: bole barks of *Rhizophora mucronata*, *Ceriops Roxburghiana* and *Bruguiera gymnorrhiza*.

The use of crude tanning materials is being fast supplanted by tannin extracts owing to the fact that the tanner can thus obtain tannin in concentrated form and the use of strong solutions is rendered possible which quickens the tanning process. This has given rise to a method by which leathers can be tanned in a week, whereas the process formerly took 6 months. The easy transport and consequent saving of freight are also of importance.

Besides their use for tanning, mangrove extracts are largely employed for waterproofing fishing nets and sails, and also to a large extent as a substitute for cutch (*Acacia Catechu*) in dyeing. PILGRIM discovered 2 materials very suitable for this purpose viz.; the waxy outer cortex barks of *Carapa moluccensis* and of *Bruguiera gymnorrhiza*. As the removal of this dead outer cortex scale is not likely to damage the trees, the supply of materials, especially of the former, is likely to be abundant.

As regards mixed mangrove extracts it is considered possible to make a useful tannin extract from suitable mixtures of 'babul' (*Acacia arabica*), myrabolan (*Terminalia belerica*) and 'goran' (*Ceriops candolleana*), the 3 standard tanstuffs of Bengal; by varying the proportions of the components, it would be possible to meet the requirements of different kinds of leather.<sup>4</sup>

173 - Utilisation of Serum in the Dilution of *Hevea* Latex. — DE VRIES, O., in *Bulletin Agricole de l'Institut Scientifique de Saïgon*, Year 3, No. 10, pp. 332-334, Tables 3, Saigon, Oct 1921. Reproduced from *Mededeelingen van het Centraal Rubberstation*, No 28. Buitenzorg, 1921.

RUBBER, GUM  
AND  
RESIN PLANTS

In the preparation of rubber, the serum residue after coagulation has been occasionally employed for the dilution of the latex, either from the point of view of economy as regards acetic acid or owing to the lack of fresh water. It appears from the results hitherto obtained, that serum thus used has no appreciable effect on the properties of the forthcoming rubber. This would seem evident from the data appended, comparing the resistance to abrasion, standard time for vulcanisation, slope and viscosity.

It this method of preparation is followed for several consecutive weeks, the natural accelerating action arising from the decomposition of the serum albuminoids will result in a speedier preparation of rubber. When, however, sodium bisulphite is added to the latex at regular intervals, the time taken for vulcanisation is not affected to any noticeable extent, if at all. The use of old serum tends however to encourage more rapid vulcanisation.

Apparently also with latex thus diluted, the composition of the liquid in which the rubber globules are suspended remains the same or perhaps only slightly changed, owing to the fact that to obtain the serum, the latex was coagulated with acetic acid. The following data indicate the relative effects of dilution with water and serum on the time taken for vulcanisation.

Latex diluted at 15 % with water, standard time for vulcanisation	120 min. at 7.5 %	125 min.
"    "    "    "    "    serum    "    "    "    "	105 "    "	110 min.
Non-diluted . . . . .	105 "    "	

These results were obtained with a coagulum which was converted into crêpe 5 hrs. after coagulation.

By diluting the latex at 7.5 % rubber content with water and serum in proportions so that the serum dilution is equal to a water dilution of the latex at 15 %, the time for vulcanisation amounted to 120 min., *i. e.* the same as with latex diluted with water at 15 %. After conversion into crêpe the day following the figures were :—

Latex diluted at 15 % with water, standard time of vulcanisation	= 110 min. at 7.5 %	120 min.
"    "    "    "    with serum    "    "    "    "	= 95 "    "	
Non diluted . . . . .	= 95 "	

The fact still remains unexplained that when serum is employed, the vulcanisation appears to advance more quickly. However, the results of experiments already made indicate that the time necessary for vulcanisation of rubber depends more especially on the concentration (composition) of the liquid when the coagulation takes place, *i. e.* the quantity of serum with which it is associated.

174 - Observations on the Camphor Plant (*Blumea balsamifera* D. C.) in Indo-China. -- VERNET, N. G. in *Bulletin agricole de l'Institut scientifique de Saigon*, Year 3, No. 11 pp. 315-353. Saigon, Nov. 1921.

As a result of a communication received from GARNIER (Directeur de l'Agence Economique de l'Indochine) dated Feb. 11, 1920 with reference to the possible utilisation of the Indo-Chinese camphor plant (*Blumea balsamifera*) for the extraction of borneol, specimens from various quarters have been distilled to test their possible value, according to directions given by GARNIER in conjunction with Prof. PERROT (Directeur de l'Office National des Matières premières pour la droguerie, pharmacie, distillerie et parfumerie). The Bussy apparatus used in the "Institut Scientifique de l'Indochine" for distillation has already been described (1)

The results obtained combined with records concerning the preservation of samples have made it possible to compare the borneol yields derived from leaves : 1) submitted to varying periods of preservation ; 2) distilled fresh or dried ; 3) of varying age ; 4) from districts where after collection of the leaves there has been some defect in the preparation. Unfortunately up to the present it has not been possible to study seas-

(1) See R. Oct. 1920, No. 1030. (Fd.)

onal influence. Apart from the data given as regards badly preserved or insufficiently dried samples, etc., the author gives a table showing all the superior yields obtained from dried leaves with a note that their condition of dryness appeared satisfactory, the leaves not having fermented and showing no sign of mould. Taking the samples from Quang-Khe as an example, the data are as follows: weight of leaves distilled, 41 kg.; crude camphor obtained 0.51 kg.; yield per 1000 12.44 kg.; essences, trace. Comparing these figures with those for samples from various other districts the yield of crude camphor, varies from 7 to 12 per 1000.

The relation between the yield of camphor and of essence is worth noting. The fact that certain samples with a high camphor content showed only traces of essential oil may be attributed either to the transformation of the latter into camphor by oxidation in air or to speedy evaporation of the essence during dessication. This is still an open question, but as regards industrial value there does not appear to be any advantage in undertaking the laborious operation of dessication of the leaves before proceeding to distillation, and it is advisable to proceed directly with the treatment of the green leaf immediately after plucking.

The question has arisen as to the economic value of the distillation process. MAGEN "Chef du Service Agricole de Cochinchine", forwarded to Giaray a request for an estimate of the costs of collection of leaves from an area covered with a very thickly growing mass of *B. balsamifera* and the information supplied to him by ANGLÈS, "Chef de la Station de Giaray", is as follows: 500 plants of *Blumea*, age from 1 to 2 years give 225 kg. of leaves, and the cost of collection amounts to \$6.00 (estimated yield per plant is 0.45 kg.). Estimated cost of collection of 1000 kg. is \$24.00.

Until a more advantageous arrangement is made both as regards collection cost and a regular sale it seems doubtful whether the utilisation of *B. balsamifera* can be considered industrially profitable in Indo-China.

#### 175 - Characters and Use of Cuica Resin derived from *Cercidium spinosum*. -

*Bulletin of the Imperial Institute*, Vol. XIX, No. 2, pp 144-145. London 1921.

In a previous account of the examination of "cuica" or "quika" resin (1) which is derived from *Cercidium spinosum* Tulasne, a small tree, native to Columbia, it was stated that the material was inferior to other resins for the preparation of spirit, turpentine or oil varnishes, but in order that conclusive trials might be made, a further supply was obtained from Columbia last year. The new sample examined was similar to the earlier sample, but contained a rather larger proportion of bark. The percentage composition of the present sample on analysis at the Imperial Institute, London, was found to be as follows: moisture 2.1, matter insoluble in boiling alcohol, 15.3 (consisting chiefly of bark), matter soluble in boiling alcohol (resin), 82.6, ash 2.1.

(1) See R. May 1921, No. 501. (Ed.)

After practical experiments at a varnish manufacturers; "cuica" was found to be not very satisfactory as a resin in the preparation of oil varnishes and it is considered that the only possible use to which it could be put would be in the preparation of tin lacquers in which benzol or similar solvents could be used. It appears doubtful whether it could be sold remuneratively in competition with better materials already available and it would have to be offered at a price between those for Manila resin and common resin (about £1 to £2 per cwt, May 1921), the value depending on the purity of the material.

**STIMULANT,  
AROMATIC,  
NARCOTIC AND  
MEDICINAL  
PLANTS**

- 176 - Notes on the Cultivation and Commercial Value of *Carica Papaya* in Ceylon and Future Possibilities in India: Investigations on the Composition of the Fruit. — I. SANYAL, PHANI BHUSAN, The Plant *Carica Papaya* and its Enzyme, in *The Agricultural Journal of India*, Vol. XVI, Pt. V, [pp. 496-507. Calcutta, [Nov. 1921. — II. CHALOT, C, and BONNY, R, Composition de la Papaye, in *L'Aeronomie Coloniale*, Year 6, No. 46, pp. 130-135. Paris, Oct. 1921

I. Information is given regarding the trade of Ceylon in the economy product, papaya, which up till now has been the chief source of supply to other countries, but it appears that at present the demand for unadulterated papain is in excess of the supply. From a rough estimate given as follows of the selling price and also the cost of production of papain, it appears that the papain industry in India would also be quite lucrative.

	Per acre	
	Minimum 400 trees (Bombay Pres.) lb.	Maximum 500 trees lb.
Papain at $\frac{1}{2}$ lb. per tree (in Ceylon the yield being $\frac{1}{2}$ to $\frac{3}{4}$ lb. per tree)	200	250
Selling price at Rs. 5 to 6 per lb. . . . .	Rs. 1000	Rs. 1500
Deducting the cost of cultivation, collection and preparation etc.	200	250
Profit from papain . . . . .	800	1250
Profit from fruit left after extraction . . . . .	200	250
Net profit . . .	1000	1500

The activity index (i. e. the quantity of protein digested per unit weight of papain in a fixed time and at a particular temperature) has been found to vary much in the trade samples. As estimated by the PRATT method on milk protein (*Philippine Journal of Science* (1915) 10, pp. 1-33), commercial specimens from Ceylon gave the following numbers: 0.1, 5.6, 9.7.

*Cultivation.* — Although usually propagated by seeds, recently asexual propagation (grafting) has been tried with some success in Amer-

ica (1) (*U. S. Dept. of Agr. Bureau of Plant Industry, Circular 119*) and also in Lucknow (India) (*Dept. of Land Records and Agriculture U. P. of Agra and Oudh. Bull.*). It has been claimed that trees so propagated fruit more quickly than seedlings. The latter are ready for transplanting about 1 month after germination and can be planted in their permanent positions at 10 ft. intervals a month later.

The following fertiliser has been successfully tried at the Hawaii Experiment Station (2) for young plants (in lb.):— superphosphate 800 + sulphate of potash 315 + nitrate of soda 250 + sulphate of ammonia 190 + black sand (volcanic ash), 445. This has been applied at the rate of 1 lb. per tree at planting time. In the Bombay Presidency, house or farmyard manure at the rate of 20 cartloads per acre has been used with success. It has also been found that 2 ploughings and 2 harrowings just before sowing improved the growth of the plants.

It is interesting to note with reference to the production of both male and female flowers that on many occasions male flowering plants have been found to change their sex *e. g.* a tree 1 ½ years old had produced only staminate flowers (1); the top of the tree was cut off and leaves plucked. After some months new branches appeared and these bore fruit.

I. II. COMPOSITION AND COMMERCIAL VALUE. — The general composition of the papaya fruit is shown by the following percentage analysis, water 90.75, protein 0.80, fat 0.10, nitrogen free extract 6.32, fibre 1.09, ash 0.94. The most important property from a biochemical point of view is the proteolytic power possessed by the latex of the fruit (2). In order to make a comparison between the analyses of several different seedling strains, the authors (II) have included a reproduction of records kept at the Hawaii Experiment Station, relative to strains coming from Trinidad, South Africa, Honolulu, Barbados, Tahiti and Panama. Apparently the sugar content consists principally of invert sugar, only traces of sucrose being present.

These records also include data with regard to the composition at various stages of maturity. The insoluble solids are about 3 % in the green and decrease to about 1 % in the ripe fruits. The ash, acid and protein occur in small quantities and are quite constant. The sugars in the green fruit do not exceed 2 % but increase rapidly as the fruit increases in size and ripens.

(1) In the *Manual of Tropical and Sub-Tropical Fruits* (Wilson Popenoe), Chap. V'I, p. 234 (Papaya and its Relatives), it is stated that "later experience has shown that when propagated by this means in Florida, a given variety degenerates rapidly, and in the third and fourth generation from the parent seedling, the grafted plants make very little growth and their fruits are small and practically worthless. The explanation of this behaviour has not been found, nor is it known whether it will occur in other regions but its effect in Florida has been to do away with grafting and cause all growers to return to seed propagation. (*Ed.*)

(2) For Papaya in Hawaii See R July 1914, No. 613. (*Ed.*)

**PREPARATION OF CRUDE PAPAIN.** — A sample of papain prepared at Pusa (I) was found to contain the following percentages; total nitrogen 9.10, albuminoid nitrogen 2.44, ammoniacal nitrogen 0.59, ash 6.92, lime 1.21, magnesia 2.19, potash 0.69, soda 0.60, phosphoric acid 0.96.

A medium sized fruit will furnish at least 100 gm. of latex. The author (I) describes the various methods of purification of crude papain and adds details of the determination of proteolytic activity of the papain purified in these various ways at Pusa, the figures showing that the samples thus prepared, compare favourably with the best marketed products from the Philippines, Mexico or Ceylon. He draws attention to certain points worthy of attention in the preparation process and in order to ascertain the effect of temperature and reaction of the medium on the rate of action of papain, tests were made with results indicating that the sample acted best in neutral and very slightly acid solution. A small quantity of alkali was found to decrease the activity considerably, but it did not totally stop it, as would be the case with pepsin. The fact that the quantity of coagulable protein digested was so great at temperatures as high as 80, 90 and 95° C no doubt explains why a few pieces of unripe papaya will very quickly soften almost boiling water.

#### FRUIT GROWING

177 — **Banana-Growing in Porto Rico.** — GONZÁLES RÍOS P. in *Gobierno de Puerto Rico, Departamento de Agricultura y Trabajo. Estación Experimental Insular, Río Piedras. P. R. Boletín* No. 25, 30 pp., figs. 10. San Juan, 1920.

The chief banana growing countries are Central America and the Antilles; the largest quantities being produced at Costa-Rica and in Jamaica. The banana is the favourite fruit at Costa-Rica, the green varieties forming the principal food of the poorer classes. The whole crop is consumed in the country, and until quite lately it not infrequently happened that St. Domingo bananas were offered for sale in some of the markets of the island.

At Porto-Rico, the banana has never been systematically and scientifically cultivated and the tree may be said to grow wild.

Most of the districts where coffee is cultivated, such as Yanco, Lares, Adjuntas, Utuado, San Sebastián, Maricao, etc., are great banana-growing centres, for the tree affords an excellent shade to the coffee plantations, and the workers receive most of their wages in the form of the fruits.

Banana-growing in Porto-Rico has a great future before it.

The main object of the Bulletin analysed is to classify the different varieties of banana trees found in the island, and to describe some of the cultural experiments which have been made. It also gives an account of the cultural methods now employed and those which should be adopted.

The following varieties growing in Porto Rico are described by the

(1) See *R* Feb 1916, No 182. (*Ed.*)

(2) See *R*. July 1915, No. 820 (*Ed.*)

author: "Guineos dátiles" (*Musa sapientium*) — guineos enanos (*M. Cavendishii*) — chamaluco (*M. normalis*), the fruits of which are used for cooking while still green — "guineo gigante", or "guaranes" (*M. sapientium*) with large bunches; this is the variety specially grown in Jamaica, and supplies most of the bananas exported to the United States, plátano común, plátano enano, plátano congo, plátano harton, plátano dominico, plátano maricongo, all varieties of *M. normalis*; the three latter are so similar to "plátano común" (having only a few more fruits in the bunch), that they may be regarded as one variety — "guineo morado" (*M. sapientium*) — "guineo gigante enano", viz. a dwarf tree with very large fruits (*M. sapientium*), one of the best varieties for cultivation.

The disease known as "el mal del plátano", which is due to *Fusarium cubense*, is a serious danger to the banana-tree in Porto-Rico. At first the trees grow vigorously, but when the fruiting season approaches, the petioles begin to turn yellow and the leaf-blades assume a chocolate colour and fold in two throughout their length.

Any fruit-bunches produced are usually badly developed, or if owing to the great fertility of the soil, bananas are obtained the first year, no fruit is borne afterwards. The pathogenetic agent lives as a saprophyte in the soil. It is propagated by the seeds or by mechanical distribution. Since it lives in the interior of the tissues, fungicides are of little avail, and recourse must be had to preventive measures.

Few insects attack the banana in Porto Rico and cause no serious injury. The author mentions the "caculo achocolatado" (*Phyllophaga* sp.) which eats the leaves of the banana and of several other plants, and the "vaquita" (*Diaprepes* sp.).

In conclusion he describes the preparation of banana meal, known also as "bananina" or "nusarina", and gives various simple recipes for its use.

## LIVE STOCK AND BREEDING.

178 — The Effic. of Chloropicrin Fumes on *Argas reflexus*. — REMY, M. P., in *Comptes rendus de l'Académie des Sciences*, Vol. 172 (Meeting of June 20), No. 27 pp. 1619-1624. Paris, June 1921.

HYGIENE

*Argas reflexus* is a parasite causing great mortality in pigeon lofts and sometimes producing serious affections in man. The destruction of this pest is a very difficult matter, for it can remain without food for several years and none of the insecticides hitherto used are absolutely certain in their effects. This does not apply however to the fumes of chloropicrin which have proved to be highly toxic in the case of other insects also (1). The author has found that if *A. reflexus* is exposed to these fumes paralysis ensues which always ends in death. No experiments

(1) See R. Jan 1920. No 58. (Ed.)

on a large scale have been made but doses of 20 to 30 gm. per cubic metre seem the most effective. The fumes should be allowed to act all day and if masks are worn there is no danger in the operation. As the hatching period lasts from 8 to 15 days, a second treatment 1 month after the first will be necessary, in order to destroy the mites that have hatched out last.

179 - **The Autopyotherapeutic Treatment of Strangles.** — MONBET, M. (Vétérinaire-major), in *Revue Vétérinaire*, Vol. LXXIII, Third Series, Vol. II, pp. 338-344. Toulouse, June 1921.

The excellent results obtained by the pyotherapeutic treatment of contagious lymphangitis in the horse suggested to the author that the same methods might be applicable to strangles which is the chief pyogenic equine disease.

The technique used was a series of autopyotherapeutic injections. The pyovaccine was prepared according to the method described by BELIN, in the *Bulletin de la Société centrale de Médecine vétérinaire*, of Feb. 28, 1919, p. 73.

Injections were made into the muscles of the central region of the collar at equal distance from the mastoid-humeral, the upper edge of the collar, and the front edge of the shoulder.

This region is first shaven and then disinfected by painting with tincture of iodine.

The injection is made by means of the short needle used for intra-dermo-palpebral maleinage attached to a 5 or 10 cc. Pravaz syringe. The amounts used are as follows: 1) four first doses increasing from 1 cc. — 1.5 cc — 2 cc — 2.5 cc. on the first four days — 2) Two doses of 2.5 cc. on the fifth and sixth days.

The experiments made on 4 mares showed that: strangles can be cured by autopyotherapeutics; this treatment, at all events if the technique described in this work is adopted, is perfectly safe; it seems to check the development of specific inflamed adenoids, but has little perceptible effect upon the course of catarrhal local affections.

180 - **Vaccination of Cattle against Anaplasmosis; the Results of Inoculating High-Class Breeding Animals with Sheep and Goats' Blood infected by Repeated Transmission.** — LIGNIERES, J., in *Bulletin de la Société de Pathologie Exotique*, Vol. XIV, No. 8, pp. 459-460. Paris, October 12, 1921

The author has been able to prove from his experiments in the vaccination of cattle against anaplasmosis, that by using the blood of sheep or goats which has been infected by repeated transmission, strong reactions requiring special treatment, but not necessarily terminating fatally, are produced in pure-blood breeding stock (1).

The natural resistance to *Anaplasma argentinum* conferred upon these cattle by such vaccination is a very important point and has been

(1) See R. April 1920, No. 438. (Ed.)

the subject of careful study on the part of the author. The results hitherto obtained have been very encouraging. In every case the greatest immunity to natural anaplasmosis has been shown by the youngest animals that have been repeatedly inoculated.

An actual proof of the value of such treatment is given by the experience of a large Argentina stock breeder who was willing to expend considerable sums on supplying breeding-cattle for districts infested with piroplasmosis and anaplasmosis. He immunised 200 of these animals in 2 series, adopting the method employed by the author. Six months later he sent for a cow from the infected region and inoculated with the blood of this animal 6 vaccinated cattle and 2 which had not been vaccinated. The latter became seriously ill and one died. Of the 6 vaccinated individuals, 4 bore the treatment very well, in 2 there was a reaction which in one case terminated fatally. Laboratory examination revealed the presence of *Anaplasma argentinum* in the blood corpuscles of all the diseased animals.

This searching test would seem to prove without any possibility of error that the method employed is thoroughly effective.

181 - "Ghedda", or Hemorrhagic Septicemia of the Dromedary. — DONATIEN, A., in *Archives des Instituts Pasteur de l'Afrique du Nord*. Vol. I, No. 3, pp. 242-249. Tunis, 1921.

This is an epizootic disease which must be very wide-spread, being known to the Arabs of numerous tribes as "Ghedda", or under some almost identical name.

From its symptoms and the lesions produced, "ghedda" may be regarded as nearly allied to the forms of hemorrhagic septicemia attacking horses, cattle, sheep, dogs, etc. The probability of this kinship is strengthened by the difficulty or impossibility of transmitting these manifestly contagious diseases by means of inoculation with the humours or organs of infected animals.

Although in other species certain microorganisms, especially *Pasteurella*, have been found to play at least a secondary part, no parasites of this kind have ever been discovered in the case of the camel.

Thus the primary and secondary virus of "ghedda" are still unknown.

182 - Note on the Natural Spirillosis of the Rabbit (*Spirochaeta cuniculi*). — I. LEVADITI, G. MARIE, A., and NICOLAUS, S., Virulence pour l'homme de la spirillose spontanée du lapin, in *Comptes rendus de l'Académie des Sciences*, Vol. 172, No. 34, (June 13, 1921), pp. 1542-1543, bibliography of 5 works, Paris, 1921. — II. RUPPERT, F. (Mitglied des Staats-instituts für Experimentelle Therapie), Über eine durch *Spirochaeta cuniculi* hervorgerufene kontagiöse Geschlechts-krankheit der Kaninchen (Kaninchen Spirochaetose), in *Berliner Tierärztliche Wochenschrift*, Year XXXV11, No. 42, pp. 493-496, 4 figs. bibliography of 18 works. Berlin, October 20, 1921.

I. — The authors have studied from the microbiological, histological and pathogenetic standpoints a spirochaete disease of the rabbit characterised by scabrous papulae occurring on the reproductive organs and nostrils.

This malady has been recorded in Austria, Germany and Holland. It is produced by a spirochaete with much morphological resemblance to *Treponema pallidum*.

The histological researches and the data connected with this disease have been dealt with in a paper written in collaboration with ISAÏCU (1) and brought before the "Société de Biologie". Experiments have proved that *Spirochaeta cuniculi* is not pathogenetic to man.

II. — Detailed information respecting: the history and etiology of rabbit spirillosis; the morphology of the pathogenetic agent; the results of natural and artificial infection; the symptoms, pathological anatomy and microscopic evidence of the disease. As regards treatment, the author states that good results have been obtained by doses of 0.04 gm. to 0.06 gm. of "Silbersalvarsannatrium" per kg. of live weight.

Rabbits after having been cured, can again contract the disease, which proves they have not acquired immunity.

#### FEEDS AND FEEDING

183 — A Calculation of the Amount of Food necessary for Stock, especially when Grazing, per 500 kg. of Live Weight. HOLDEFLISS, P., in *Deutsche Landwirtschaftliche Presse*, Year XLVIII, No. 94, p. 60; Berlin, November 1921

In order to allow a uniform comparison of the amount of food required by stock, the calculation is based on a live-weight of 500 or 1000 kg.

KÖHN and KELLNER's rationing tables are also based on 500 kg. of live-weight. It is however well-known that 500 kg. of live-weight have a significance differing with the size of the animals considered. In practical rationing these conditions are taken into account, maximum or super-maximum amounts being given to small animals, and minimum quantities to large animals. It would be better to use determined numerical proportions; simple coefficients or connection factors could easily be employed in reckoning the ordinary rations. This method is particularly useful in calculating the production of pastures, especially when the animals belong to different species and are of varying sizes.

According to RUBNER and KELLNER the amount of food required is in more direct relation to the body-surface than to the live-weight.

In order to obtain numerical proportions that can be used, the author has devised the following formula where  $a$  represents the live-weight in pounds of 500 grams,  $Fu a$  represents the amount of food required per head, and 1 the amount necessary for 1000 pounds of live-weight:

$$1 : Fu a = \sqrt[3]{\frac{1000^3}{a^3}} : \sqrt[3]{a^3}$$

The cube-root of the live-weight is unity: its square is the ratio

(1) LEVADITI, M. and ISAÏCU, in *Comptes rendus de la Société de Biologie*, Meeting of June 11, 1921.

with the body-surface. The amount of food required for the live-weight is therefore :

$$Fu a = \frac{\sqrt[3]{a^2} \times 1}{\sqrt[3]{1000^2}}$$

For 1000 pounds of live-weight, the formula is as follows :

$$Fu \times 1000 = \frac{\sqrt[3]{a^2}}{\sqrt[3]{1000^2}} \times \frac{1000}{a} = \frac{10}{\sqrt[3]{a}} = f$$

By giving  $a$  increasing values, a decreasing logarithmic series is obtained for the values of  $f$ .

TABLE I. — *Correction Coefficients  
for the different Values of Live-Weight.*

$a$ Live-Weight in kg.	$f$ Correction Coefficient	$a$ Live-Weight in kg.	$f$ Correction Coefficient
0.5	10.00	200	1.36
1.0	7.94	250	1.26
2.0	6.30	300	1.19
3.0	5.50	350	1.13
4.0	5.00	400	1.08
5.0	4.64	450	1.04
12.5	3.42	500	1.00
25.0	2.72	550	0.97
37.5	2.37	600	0.94
55.0	2.15	650	0.92
62.5	2.00	700	0.89
75.0	1.88	750	0.87
87.5	1.79	800	0.86
100.0	1.07	850	0.84
150.0	1.49	2 850	0.56

The results obtained on multiplying by the coefficients  $f$  the values calculated for 500 kg. of live weight, when compared with the figures obtained empirically, have shown that these coefficients may be considered exact within considerable limits.

When it is a question of determining the production of a pasture, the correction by means of these coefficients also gives more accurate results. Table II gives two instances of such a calculation.

TABLE II. — *Calculation of Production of 2 Pastures.*

No. and kind of animals at grass	Average live-weight kg	No of days of grazing	Total production expressed as grazing-days per 500 kg. of live weight		
			Simple calculation	Factor /	Corrected calculation
Pasture I					
5 cows . . .	500	80	400.0	1.00	400.0
2 oxen . . .	700	50	140.0	0.89	124.6
11 calves . . .	300	120	792.0	1.19	942.5
10 sheep . . .	62.50	150	187.5	2.00	375.0
4 colts . . .	350	150	420.0	1.13	474.6
Total . . .	—	—	1 939.5	—	2 316.7
Pasture II					
5 cows . . .	450	80	360.0	1.04	374.4
2 oxen . . .	600	50	120.0	0.94	112.8
14 calves . . .	250	120	840.0	1.26	1 058.4
13 sheep . . .	50	150	195.0	2.15	419.2
4 colts . . .	250	150	300.0	1.26	378.0
Total . . .	—	—	1 815.0	—	2 342.8

If the simple (uncorrected) calculation is taken as the basis, pasture II will have produced less than pasture I, but if the corrections are made by means of the coefficients for the different classes of animals, the production of pasture II is greater than that of pasture I.

Berlin, 1921.

I. THE METHODS HITHERTO EMPLOYED IN THE DISINTEGRATION OF STRAW, AND THE CHIEF RESULTS OBTAINED. — The final object of all these methods is to increase the digestibility and forage value of straw

(1) See R., April 1921, No. 406. See also MAGNUS, H., *Theorie und Praxis der Strohaufschliessung* (Aus dem Laboratorium des Kilegsausschusses für Ersatzfutter). Verlagsbuchhandlung Paul Parey, Berlin, 1919 and VON WISSEL, Beitrag zur Ermittlung eines einfachen und zuverlässigen Verfahrens die Höhe des Aufschliessungsgrades von Kraftstroh und dergleichen analytisch festzustellen, *Die landwirtschaftlichen Versuchs-Stationen*,

in general by treating it with chemical agents having the power to free the fibre from its surrounding elements, especially lignin, so as to assist the bacteria in breaking up and destroying the cellulose. It is, however, now admitted that the complete removal of the lignin is not necessary in the disintegration of straw, but that it is rather a question of softening the crude fibre and breaking down the strong connection between the lignins and the cellulose. Whereas satisfactory results have been obtained with alkalis and caustic soda, the disintegration of straw by the action of acids was a failure. The researches of PRINGSHEIM and MAGNUS made clear the changes undergone by the straw during its treatment with caustic soda, quick-lime and carbonate of soda. During disintegration with caustic soda, first the silicic acid and then the lignin are removed.

The best method of disintegration is BECKMANN'S, the straw being treated cold with alkalis and under ordinary pressure.

The author carried out a series of feeding experiments using straw that had been disintegrated by the three alkaline processes, and ascertained the loss of crude nutrient substances entailed by the disintegration. The disintegration of straw under pressure with caustic soda caused the destruction of part of the organic matter containing all the groups of nutritive substances.

Disintegrated straw from different species of plants was fed to sheep and its effects compared with crude straw of similar origin.

The straw of autumn cereals lends itself best to disintegration. After treatment with 3.5, or 7 % caustic soda the digestibility of the straw was increased respectively 72 and 94 %.

The results so far obtained may be summarised as follows : the increase in the food value due to disintegration, which shows itself in the increased starch value, is very great in the straw of autumn cereals, but slight in straw from Leguminosae and Cruciferae.

II. DISINTEGRATION OF STRAW BY COLD SODA LYE ACCORDING TO BECKMANN'S PROCESS. — This process, which has been patented, is carried out in the following manner by the "Veredelungsgesellschaft für Nahrungs und Futtermittel, Bremen and Berlin": chopped straw is

Vol. XCVI, Parts 5-6, pp. 263-275 Berlin, 1920 — In this contribution to the search for a simple, sure process for the analytic determination of the extent to which the straw had been disintegrated by the treatment ( "Kluftstroh" ) etc., the results obtained by the different processes are given viz.: 1) phloroglucin test; — 2) WEENDE's method — 3) gravimetric method — 4) volumetric method — 5) WOHL's calcium chloride method. The results show that in order to ascertain the extent to which the straw has been disintegrated, it is necessary not only to analyse the straw that has been treated but also the crude straw, and further the disintegration process adopted must also be known. A short description is given of 3 hitherto untested processes invented by: 1) WAENTIG and GIERSCHE (see R. Dec. 1921, No. 1244) — 2) MACH and LEDERLE, *Die Landwirtschaftlichen Versuchs-Stationen*, Vol. XI, p. 274. Berlin, 1917 — 3) WILLSTÄDTER (see R. Dec. 1921, No. 1244). (Ed.)

placed in flat boxes made of wood or tin (the fixed height being about 50 cm.: the surface area, 2 sq. metres per quintal of straw); 8 times its weight of 1.5-2 % soda lye is then added and allowed to act for 12 hours; the mixture requires stirring from time to time.

The boxes should be put in tiers so that the lye, which is used 3 times, can be collected and used successively in each of the lower boxes. The alkaline lye can easily be removed from the straw by washing.

FINGERLING has compared the digestibility of straw disintegrated with a cold ("Kaltstroh"), and a hot lye respectively. He obtained the results given in Table I.

TABLE I. — *Comparative Digestibility of Straw disintegrated by COLSMANN and BECKMANN'S Processes.*

Nutritive substances	Straw disintegrated by boiling (COLSMANN process)	Straw disintegrated by cold lye (BECKMANN process)	
		for 3 days	for 12 hours
Organic matter . . . . .	58.77 %	72.76 %	71.08 %
Nitrogen-free extracts. . . . .	35.89	79.59	63.55
Fat . . . . .	—	69.01	84.76
Crude fibre . . . . .	73.28	70.36	78.86

The author uses a BECKMANN process plant at the Agricultural Institute of the University of Königsberg. The average water consumption is 4.02 cubic metres per quintal of crude straw; this gives an average yield of 4.1 quintals of damp, disintegrated straw containing on an average 16.9 % of dry matter. The loss in dry matter was 22.4 % instead of 37.16 %, as is the case with the COLSMANN process.

It takes 20.8 litres of cold soda lye to disintegrate 100 kg. of crude straw, but 16 litres of boiling lye are sufficient. The content of digestive nutritive substances determined by the author is given in Table II.

HANSEN has also made experiments to find out the food value of straw disintegrated with a cold lye and a boiling lye respectively. It was impossible to make accurate determinations in the case of horses (which prefer straw that has been disintegrated with cold lye), on account of the nature of their performance. On the other hand accurate experiments were carried out for 3 months with milch cows. The deviations observed in milk yield and fat production were very slight.

HANSEN found from his experiments that disintegration for 3 days with cold lye gives to rye straw a nutritive value equivalent to that resulting from treatment with boiling lye according to COLSMANN'S process. Cold disintegration has also this additional advantage over boiling, that it can be carried out on any agricultural farm possessing a suf-

ficient water supply, for the plant required is very simple and much less expensive than that used in the COLSMANN process.

TABLE II. — *Digestible Nutritive Substance Content of Straw disintegrated with Cold Lye ("Kaltstroh").*

Nutritive substances	Straw disintegrated by cold lye		Dry matter of disintegrated straw	
	treated for 3 days	treated for 12 hours	treated for 3 days	treated for 12 hours
Dry matter . . . . .	16.29 %	16.81 %	100 %	100 %
Nitrogen-free extracts . . . . .	4.18	4.63	25.59	27.54
Crude fat . . . . .	0.18	0.19	1.10	1.11
Crude fibre . . . . .	6.66	6.44	40.93	38.32
Starch value . . . . .	9.50	9.72	58.32	57.79

III. DISINTEGRATION OF STRAW WITH MILK OF LIME BOTH WITH AND WITHOUT PRESSURE. — The experiments of the authors have demonstrated that the disintegration of straw by milk of lime also causes greater losses of organic matter when the process is carried out under pressure than when no pressure is applied. The fibre does not appear to be attacked. With this process the amount of investing substances removed (lignin + silicic acid) is less than when caustic soda is used, but as the proportion of the organic matter and especially the crude fibre is almost as large in the resulting product as in straw that has been disintegrated by soda, it is evident that the amount of lignin present in a disintegrated straw is not an exact measure of the extent to which the process has been carried out.

The starch value of straw disintegrated by quick-lime is much superior to that of crude straw, being in the first case 48.68, and in the second 13.29.

The above shows that disintegration with lime with or without pressure increases the food value of the straw almost as much as treatment with caustic soda.

The damp, disintegrated straw was eaten by the stock without any bad effects, no digestive disturbances being observed. The lignin was completely undigested. The digested portion of the crude fibre, as determined by the methods of WEENDE and CROSS, had almost the same composition as refined fibre.

IV. DISINTEGRATION OF STRAW WITH CARBONATE OF SODA. — The straw is boiled for 3 hours with 8 times its weight of an 8 % solution of carbonate of soda, just as in the cases where quick-lime or lime is used. The fibre is not attacked, but the pentosans are probably much affected.

Experiments in feeding sheep on rye-straw disintegrated by boiling

with 8 % milk of lime under pressure for 5 hours and with carbonate of soda of the same concentration, but for a shorter time, have shown that the latter process is the more effective. The respective digestibility coefficients of the rye straw in either case are given in Table III.

TABLE III. — *Digestibility coefficients of rye-straw disintegrated with lime and carbonate of soda respectively.*

	Disintegration with lime	Disintegration with carbonate of soda
Organic matter . . . . .	53.4 %	60.6 %
Nitrogen-free extracts . . . . .	32.2	41.0
Crude fibre . . . . .	75.7	80.2

The starch value of the straw disintegrated by lime was 47.1, whereas that of the straw treated with carbonate of soda was as high as 55.6.

The crude fibre estimated by CROSS differed from that determined by WEENDE'S method in having almost the same composition as pure fibre. In the same manner the digested portion of CROSS'S crude fibre was entirely similar in composition to the digested portion of the pure fibre.

185 — **Researches Made in the United States on the Sodium Chloride Content of Stock Feeds.** — FRAPS, G. S. and LOMANITZ, S., in *Texas Agricultural Experiment Station* (Division of Chemistry), *Bulletin* No. 271, pp. 5-14 College Station Texas, October, 1920.

In estimating the sodium chloride content of a mixed feed, it is necessary to know the amount of this substance in the ingredients used. The sodium chloride content of a mixture can be calculated either from the average composition, or from the maximum of each of the ingredients. The excess of salt found over that calculated is to be regarded as due to an addition.

The authors have determined the chloride content (expressed as sodium chloride) in a number of feeds by the method of incineration in the presence of sodium carbonate. As the Official A. O. A. C. (Association of Official Agricultural Chemists), method was too lengthy for examining a large number of feeds, the authors tried a more rapid method (which they describe in detail), giving results that agreed well with the official system.

The following Table shows that all unmixed feeds except lucerne, molasses and some meat products are low in chlorides.

An approximate method for estimating the added salt in a mixed feed is to subtract 1 % of the sum of the lucerne and molasses from the salt content calculated to sodium chloride, or better still, by comparison with the sodium chloride averages obtained for the ingredients of the feed.

TABLE.

Feeds	No. of samples	Minimum	Maximum	Average
Lucerne Hay (western) . . . . .	14	0.42	1.89	0.98

186 - **Gemsbok Beans Budlake (*Bauhinia esculenta*) as Feeds for Cattle.** — See No. 162 of this Review.

187 - **The Change in the Fat of Peanut Fed Rabbits.** — DOWELL, S. T. (Oklahoma Agricultural Experiment Station, Stillwater), in *Science*, Vol. LIII, No. 1377, p. 487. Lancaster, Pa., May 1921.

In order to determine whether an animal in starving uses the liquid fat more rapidly than the solid, rabbits were fed on peanuts and alfalfa for six weeks. One of the rabbits was killed at the end of the feeding period and the others were killed after starving for 3.5 and 7 days respectively.

The iodine numbers of the kidney fat and the back fat were determined. The results are shown as follows:

Rabbit. No.	Iodine number of back fat	Iodine number of kidney fat
1 (killed after feeding period) . . . . .	90.23	98.00
2 " " starving 3 days) . . . . .	78.34	97.92

4 " " " 7 " . . . . .	66.22	92.36

The percentage of liver fat extracted by ether was respectively 8.15, 17.04, 19.18 and 20.9 for the rabbits, series 1-4, but the iodine number remained constant, showing values from 98 to 104.

The results indicate that the liquid fat of an animal during starvation is used more rapidly than the solid, and the liquid fat of the back or subcutaneous fat is more rapidly consumed than that of the kidney.

This investigation is important from the point of view of the soft pork question from peanut fed animals. It suggests that if both liquid and solid fat were fed at the same time, greater proportion of liquid fat would be used to meet the energy requirements of the body, and this would make it possible to overcome the softness of the pork of peanut fed hogs.

Results obtained in the spring indicated that it is preferable to feed the peanuts with other feeds for 70 days rather than to feed for 40 days with peanuts alone and then to finish with other feeds.

The author intends to repeat this work, using pigs as his subjects instead of rabbits.

188 - **The Dongolao Horse.** — TARANTINO, G. B. (Osservatorio zootecnico della Colonia Eritrea), in *Allevamenti*, Year II, No. 7, pp. 196-198, figs. 5, No. 8, pp. 231-232, figs. 2. Palermo, July 1, 1921, August 1, 1921.

HORSES

In Eritrea and especially at Hamasien excellent horses used formerly to be bred. At the present time, horse-breeding is no longer practised and horses are imported, the greater number coming from Abyssinia and specially from Tigrai. Two horse-breeding attempts made by the Italian Government in 1903 at Godofelassi, and in 1918-1919 at Sahel (Nacfa) were unsuccessful. In the districts of Barca, Gasc and Setit, which are the most suited to horse production, there are a few private stud-stations belonging to the Chiefs of the tribe.

The main cause of the almost complete disappearance of horse-breeding in Eritrea is the prevalence of horse-pest. The author states, however, that this disease could easily be prevented by the help of well-directed prophylaxis.

The horse bred in Eritrea and in general throughout Abyssinia, is of the Dongolao or Dongolaw type, so called from Dongola, its place of origin the northern portion of Nubia and the Sudan. It is clearly distinct from the eastern type and is probably the result of a very old cross between native and western breeds. The Dongolao is a luxury horse and highly prized. Its conformation is good, but the joints are weakened by the practice of hobbling from earliest youth whenever they are turned out. The measurements taken by the author were as follows: height at withers 1.45 m., height at croup 1.45 m., height at cannon bone 0.45 m., length of head 0.54 m., length of neck (sinciput withers) 0.87 m., length of neck (throat-chest) 0.57 m., circumference of thorax 1.10 m., circumference of abdomen (umbilicus) 1.26 m., length of trunk (point of shoulder to croup) 1.05 m., width of croup 0.48 m., distance between the shoulders 0.48 m., length of shoulder 0.61 m., circumference of knee 0.30 m., circumference of hock 0.37 m., circumference of cannon-bone 0.18 m.

The Dongolao is exclusively a saddle-horse. The methods of breeding leave much to be desired. The stallions and broodmares do not receive the care necessary and the colt sucks its dam for 40 to 60 days and is also given cows' or camels' milk. When about 2 years old, a child is put on its back and the animal is led to the pasture or watering-place, two of its feet being hobbled laterally or diagonally in order to accustom it to amble.

When it is about 30 months old, it is mounted by a good rider.

The author describes the various components of the harness of the Dongolao horse and concludes by expressing the hope that the Government will take measures to arrest the retrograde movement in the breeding of this fine animal. This could be done by choosing Arab sires, by constructing shelters to protect the horses during the night from the attacks of many insects that spread diseases, and by feeding rather more liberal rations of barley or doura.

189 - **Essay on the Depreciation in the Market Value of Broken-Kneed-Horses.** —

NICOLAS, E., in *Recueil de Médecine Vétérinaire*, Vol. XCVII, No 20, pp. 399-407. Alfort, October, 1921.

The disputed claims that frequently have to be adjudged in this connection are of considerable importance on the economic side, and very difficult to settle on account of the small amount of assistance given by writers on the subject.

The losses the third party responsible for the accident is required to make good are of two kinds: 1) *Remediable injury*: feeding, cost of treatment, and if necessary, the expense of replacing the animal. The assessment of these damages generally comes within the scope of the judicial police and can usually be made without difficulty. — 2) *the loss due to the depreciation of the animal* should the accident have left any definite mischief or sequelae. This is where the difficulty begins. How far has the owner a right to compensation for this depreciation in the value of his horse?

The author has studied the reason for the depreciation of the broken-kneed horse, and finds it may be ascribed to the three following causes which he examines separately: 1) functional trouble, 2) possible weakness of limbs and predisposition to falling; 3) unsightly nature of the scar.

1) *Functional trouble.* — This is relatively rare. Where it exists, it gives rise to lameness and the economic loss must be estimated under this head.

2) *Possible weakness of the legs and predisposition to further falls.* — This point holds good for all horses no matter to what category they belong. It is obvious however that its importance varies with the class of animal, since the consequences of another fall should it occur, would be very different in the cases of a saddle-horse, a post-horse or draught horse. It may therefore be said that the consequences to be feared in the case of a broken-kneed horse are proportionate to  $mV^2$ . If the relative values of  $V$  are determined for galloping, trotting and walking, the necessary data for judging the depreciation caused are obtained. Thus, calculated as a function of the height  $H$  of horses, these values are, according to the authorities on the subject (1)  $\frac{3}{4}$  (no work):  $\frac{6}{4}$  (trotting);  $\frac{9}{4}$  (galloping) or as 1: 2: 3, and their squares as 1: 4: 9.

The author, in calculating the depreciation on the case of the three

(1) DECHAMBRE, *Traité de zootechnie*, Vol. 1, p. 350. (Author's note)

classes of horses, devised the following general formula summarising the total depreciation incurred by a broken-kneed horse (2).

$$\text{Depreciation} = \frac{\left( Vba - \left[ P \times p \times \frac{10}{8} \right] \right) V^2}{9}$$

As is seen, the horses are grouped in 3 categories according to the use that is generally made of them (and hence according to their paces and speed), which may be characterised by 3 types : 1) the saddle-horse of which the pace is a gallop ; 2) the post horse which trots ; 3) the draught horse which walks. These types depend to some extent on the same principle as the assessment of the depreciation and are its logical outcome. As the value of the horse before the accident forms part of the depreciation formula, the depreciation cannot be out of proportion to the worth of the animal. A horse of 500 kg. and bought for 1500 francs, whether a riding or driving horse, a trotter or walker, will be depreciated to the same ultimate extent, according to the formula, if the price of horse-meat is 2.50 fr., which is perfectly just, as the meat has not decreased in value, and therefore cannot have become depreciated. Reciprocally, the most valuable horses are most depreciated by such an accident.

3) *Unightly nature of the scar.* — This is only of importance in the case of the riding or driving horse. A broken-kneed animal cannot be used for either purpose, for it is blemished, and must sink to the level of a rejected horse. Its value is given by the following formula :

$$\text{Depreciation} = Vba - \left( P \times p \times \frac{10}{8} \right)$$

Depreciations are not cumulative, one excludes another, and it is the most important that is taken into account. Thus a horse loses nothing more of its value by breaking its knees a second time, unless the second fall produces some functional trouble that did not exist before, in which case the depreciation is estimated for lameness.

In short it is clear that if the owner claims a given sum as damages, the expert will only acquiesce if this is below the amount of depreciation which would logically follow from his deductions. The expert will however explain his views to the judge, so that he may understand that the opinion depends upon sound reasoning.

190 - **Comparative Feeding Value of Sunflower Silage and Darso Silage for Fattening Baby Beef during the Final Stage of Fattening. Experiments in the United States.** — BLIZZARD, W. L., in *Oklahoma Agricultural and Mechanical College, Agricultural Experiment Station, Bulletin No. 131*, pp. 3-7. Stillwater, Sept. 1920.

CATTLE

Experiments covering a period of 150 days conducted at the U. S. Indian School at Chilocco (Oklahoma), with 14 calves registered Hereford ♂ × Shorthorn ♀ (high grade). These animals were calved the previous

(2) The coefficient 10 which is obtained from the work capital and the flesh capital of a rejected horse may vary with the season and the place. (*Authors' note.*)

spring, weaned in October and divided into two lots, each receiving a ration of ground maize, cottonseed meal, and lucerne hay, but Lot I received in addition sunflower silage, and Lot II, darso (sorghum var.) silage.

The average percentage composition of sunflower and darso silage is shown as follows, respectively: water 71.96 and 73.11; ash, 3.23 and 1.54; protein, 2.96 and 1.91; fibre 8.67 and 6.46; nitrogen free extract 12.36 and 16.65; fat 0.81 and 0.34.

The results of these experiments (January 16 to June 17, 1920) are collected in the appended table.

These results indicate that darso silage combined with the given ration, has proved to be practically equal in value to sunflower silage for encouraging beef production

191 - **Effect of Shelter and Temperature of the Drinking Water on the Increase in Weight of Fattening Cattle (1) Experiments in the United States.** — POTTER, E. L., and WITHYCOMBE, R., in *Oregon Agricultural College Experiment Station, Eastern Oregon Branch Station, Bulletin No 183*, pp. 5-11, Corvallis, Oregon, Sept. 1921.

Experiments conducted over a period of several years at the Eastern Oregon Branch Station with cattle and dairy cows have shown that fattening cattle, fed under shelter and having access to a paddock, consume a quantity of feed equal to that consumed by animals reared in the field, and the actual gain established is comparatively negligible. The results obtained with fattening dairy cows indicated no noticeable difference whatever.

As regards the effect of the temperature of the water, results obtained with cattle stock showed that the effect is practically nil both with reference to food consumption and to increase in weight.

192 - **The Gascon and Lauraguaise Breeds of Pigs in France.** — GIRARD, Les races porcines méridionales, in *Revue Vétérinaire*, Vol. LXXIII, 3<sup>rd</sup> series, Vol. II, pp. 82-95 and 466-485. Toulouse, February and April, 1921.

It is estimated that there are over 1 200 000 adult pigs in the south of France which are unequally distributed among the 12 departments forming the secondary basins of the Aude and the Adour. These animals may be black or white, but are most commonly piebald; they form more than one-fifth of the total number of pigs in the country. The pigs of the south of France, unlike those of the North, all belong to the type with pointed snout and horizontal ears known as the "mole-headed or circum-mediterranean breed" living in Africa, and also found in Spain, Portugal, Italy and the whole of South and Central Europe. Some are pure-bred animals, others are the results of crossing the mole-headed race with English pigs or white Celtic breeds.

Taken as a whole they form a large and very distinct ethnical group, in which 5 chief races can be distinguished: the *Gasconne*, *Lauraguaise*, du *Quercy*, *Pyrénéenne* and *Périgourdine* or *Limousine* with 2 sub-races or varieties: the *Miélan* and the *Cazère*. The author while proposing to provide a detailed description of the history, habitat, centres of production, and also of the morphological and physiological characters of these breeds, deals in this paper first with the Gascon and with the Lauraguaise breeds, reserving the other for future publications.

**THE GASCON BREED OF PIGS.** — This race is now quartered at Nebouzon, a small district of Gascony enclosed by Armagnac, Couserans, Comminges, and Lomagne. Its economic capital, Boulogne-sur-Gesse, has become the centre of the production and the chief market for this breed, which although rather late in developing, is much prized and sought after, on account of its resistance to disease and the quality of its meat.

The breed is very ancient, not yet officially recognised but probably indigenous, and the original stock of all the above mentioned races, as it dates back to prehistoric times. In any case this pig has always been found both in the French and Spanish Pyrenees and its colour was always black.

The adult animal is about 0.75 m. in height (the hind quarters slightly exceed this measurement). At a year old its weight varies around 100 kg., being 150 kg. when it is 18 months old, 200 kg. at 2 years, and may reach 250 or even 300 kg., in the case of fattened animals when 30 months old: some show specimens have weighed over 350 kg.

The Gascon pig is entirely black, its skin is completely and heavily pigmented, the bristles are black throughout their length, the snout and hoofs are black without a trace of any other colour. Any white or grey markings are a proof of crossing with white English breeds, or with the Craonnaise, and disqualify the animals for breeding purposes.

The frame-work of these pigs is strong without being heavy. The skin is thick and coarse but flexible, and is covered with long stiff hairs distributed differently in the various parts of the body, but always allowing

the brown skin with its copper-coloured lights to show through. There is no dewlap or tuft. Many of the animals have on their necks, between the shoulders and the beginning of the back, tufts of longer and stronger bristles pointed in the reverse direction and forming rosettes or brushes. Such animals are much in request with pig-breeders, who declare that they are more resistant than others to changes of temperature, especially to heat.

The limbs of these swine are light and at the same time solid, indicating a strong animal and a good walker. The framework and conformation are regular, showing the type to be eumetric, rectilinear, with medium lines, though possessing a slight tendency to elongation; the body is somewhat compressed, and the outline a little irregular at the withers and hump.

The head is narrow, clearly truncated and very long, especially in the facial portion, which is straight and pointed, terminating in a small, solid, very mobile snout specially adapted to rooting in the ground. The ears are of average length, rather thin, somewhat narrow, close together at the base, and slightly divergent for the rest of their length, carried horizontally or slightly drooping, so as to form a pent-house above the eyes.

Taken altogether, the head is narrow and the outline both above and below is nearly straight thus imparting to the face its characteristic shape of a truncated cone or "moles' head".

The neck is long and fat, compressed in the region of the throat and without dewlap. The upper portion is slender and straight; it is rather narrow where it joins the shoulders but always very muscular.

The body is almost cylindrical, slightly elongated beneath the dorso-lumbar line which is distinctly straight. The chest is always a little narrow, the hind quarters on the other hand are short, oval, and broad, terminating in a fleshy well-rounded ham; the strongly developed crural masses give the hinder parts of the fattened pig the appearance known as "colt-rumped".

The abdomen is generally well-supported and round. The tail should be long strong and covered to the tip with short hairs, large at the base, tapering at the point and terminating in a tassel of long coarse hair, curly in young pigs, and straight and pendent in fat adult animals.

The height and conformation of the pigs vary greatly according to the districts where they are reared and the breeding conditions. As a rule, they are a good criterion of the fertility of the soil. The average morphological type as represented by a boar 18 months old may be described as follows:

Height at withers . . . . .	0.75 m.	Width of chest . . . . .	0.35 m.
Height of back . . . . .	0.78 "	Height of chest . . . . .	0.40 "
Height at croup . . . . .	0.71 "	Width of croup . . . . .	0.35 "
Length of body . . . . .	1.20 "	Length of ears . . . . .	0.20 "
Length of head . . . . .	0.40 "	Width of ears (at base) . .	0.10 "
Length of croup . . . . .	0.35 "	Average length of hair . .	0.06 "

The sow is always a little lower, flatter and longer.

Fattened animals are nearer the ground, more thick-set and rounder;

they have a larger collar and wider croup ; the line of the back is straighter, sometimes interrupted in the middle.

It is noticeable that after the age of 18 months the Gascon pig increases little in height and length ; it simply puts on fat which is deposited in a layer under the skin. This layer of fat may become 15 cm. thick on the back and chest, which makes the animals look thick-set and shorter.

The Gascon breed is hardy, vigorous and very prolific, but matures late. These pigs turn to excellent account the liberal rations that may be given them. When well-fed from the first, and comfortably housed in healthy, clean piggeries, the animals grow quickly and furnish a large amount of good meat from the age of 10 months. As a general rule, however, they do not fatten easily until they are 2 years old.

The only food they are given are potatoes and maize (especially the latter), mixed with pig-wash, scalded bran or crushed boiled beans. It is reckoned that, during the 3 months of fattening, the pig consumes 5 hectolitres of maize and gains about 80 kg. in weight, viz., a little less than one kilo a day.

The breed has the great merit of providing for family use the type of butcher's animal that is becoming rare in France.

The Gascon pig, when well fattened, satisfies all the requirements of the peasant consumption of the district.

Its yield is fairly high, being as much as 85 %. It gives a large proportion of very delicate fat, strong intestines and much blood (10-12 kg.). This pig is therefore very useful to the pork-butcher, and to the house-wife. The meat is excellent, of a fine red colour, very firm though tender, nutritious and of good flavour. The two elements constituting fat meat are distinct in this pig ; the fat is little dispersed and the meat is close ; nearly all the fat is in a covering layer and there is a good supply of lard. These qualities are much prized by the southern peasants who expect the pig to provide them, not only with a stock-pot, the basis of their food supply, but also with the fat required for cooking.

II. LAURAGUAISE BREED OF PIGS. — This breed deserves mention among the chief races in the South, for it is of ancient native origin and still makes its influence felt, as in the past, upon pig-breeding in the south of France. It is a near relative and cousin-german of the Gascon race, but only numbers 100 000 animals, all of which are confined to the upper basin of the Garonne. This pig is a product of the two great types, the *Iberian* and the *Celtic*, a little *Asiatic* blood having been introduced by crossing with English breeds. Its special well-defined characters due to the adaptations necessitated by the climatic and cultural conditions of the country have raised it to the position of a distinct breed. The evolution of this breed is described in detail in the author's long account of its history.

At the present time, the Lauraguaise breed which is derived from the *Iberian* and *Celtic* types, with some admixture of qualities borrowed from the *Large Yorkshire*, can be described as follows : tall, completely white, long but rather inclined to heaviness, frame strong, convex-linear, a little heavy and unsymmetrical, with "mole head", rather heavy semi-long

and semi-pendent ears. The average height of the adult animal is 0.80 m. but it varies from 0.05 m. to 0.08 m. in either direction according to the sex. The piglings of this breed which are fatter and longer when farrowed than those of other races, generally weigh 20 kg. when they are weaned (at the age of 2 ½ months). When sold at about 4 months old, their average weight is 35 kg, and under ordinary conditions they easily weigh 60 kg. when they reach 6 months. When 1 year old boars weigh 125 kg. and sows from 90 to 100 kg; after attaining their full development both weigh 200 or even 250 kg, and after fattening, may turn the scale at 350 kg.

As was said above, these pigs are quite white. The skin is completely without pigment, and is of a yellowish-white free from spots or lights. A few brown or bluish spots are not infrequent on the head or croup, but the breeders are doing their best to eliminate them.

The coarse, long, thick hair which grows freely on the withers, neck and lower portions of the limbs is of a dirty white and assumes a yellowish tinge in old animals.

The head is strong and always a little heavy. One of the chief characters of the Lauraguaise pig is the great development of the frame while the animal is still young. The boar is very large and massive with strong robust frame, well developed forelimbs, rather light hind limbs, wide, deep chest, relatively small abdomen, almost bent upwards at its posterior end.

The sow on the contrary although finer and narrower in front is remarkable for its great length of pelvis, broad quarters and prolapsed abdomen which sometimes in spite of its long legs almost sweeps the ground.

The animals of both sexes are specially noted for length of shoulders, width of chest and great development of the croup, which confer not only considerable weight, but also great body length. This may be as much as 2 metres in breeding-animals, if measured from the snout to the root of the tail. Many good specimens measure 0.90 m. at shoulder height, 1.55 m. around the chest, and 1.60 m. in length from the neck to the root of the tail.

The head is strong, somewhat heavy, narrow, and dry, a little overweighted by the ears, the profile is slightly receding, betraying a cross with the Celtic breed.

The skull is short, rather wide, with prominent occipital region and flat forehead. The face is flat, and forms a regular truncated cone, carrying a slender but very strong snout eminently adapted for rooting in the ground. The neck, which is thin at the point of attachment to the head, is very thick at its insertion on the trunk; it is muscular, very mobile and somewhat long.

Other details are given as to the body of this pig, which is well-fitted for a meat-producing animal. Its legs are also described. The two chief physiological merits of this breed which find favour with the agriculturists of the south and are the cause of its persistence in the region, are its fecundity and hardiness. The boars and sows are equally fertile and the Lauraguaise pig is strong and docile, well-adapted to sudden changes of temperature and to strong winds. It is easy to keep and a good forager.

From the economic point of view, the merits of this pig are the outcome of its origin, its conformation and its rearing. The animals grow large and fatten easily, but they do not show these qualities, at least under ordinary conditions, until they are fairly old, usually when about 12 or 14 months old.

The Lauraguaise breed thus represent a type of pig well suited to the requirements and condition of Southern countries, and though it is not perfect, nor even the best race of the region, it yet deserves to be more extensively kept.

193 - **Use of Forage Crops in the Fattening of Pigs. Experiments in the United States** (1). — ROBISON, W. L., in *Ohio Agricultural Experiment Station, Bulletin* No. 343, pp 165-222. tables 24 + figs. Wooster, Ohio, June 1921.

Experiments conducted from 1912-1918 with chiefly purebred Duroc Jersey pigs, farrowed in March and April.

Their object was to gain a knowledge of the most appropriate methods of supplementary feeding for pigs on forage. In most cases one or more groups of pigs were kept on the "dry lot" system for control purposes in order to determine the weight and economic value of the pasture crops.

Table I summarises the results of experiments made on clover pasture.

In a further experiment, the pigs were pastured on blue grass (*Poa pratensis*) with a certain amount of white clover; self-fed maize and tankage was given separately. The pigs thus treated gained at the rate of 1.16 to 1.15 lb. daily per head; and per 100 lb. of gain, consumed 320.6 and 321.5 of maize and tankage respectively.

A number of experiments were conducted with rape pasture. The results of several are summarised in Table II.

Three experiments (Nos. 11, 12, 13) were made with pigs weighing respectively 99; 79; and 68 lb. pastured on rape with a supplementary feed of shelled maize + tankage, in order to compare the self-feeding with hand-feeding. The self-fed lots gained weight more rapidly than the hand-fed, although in 2 experiments with younger pigs, the hand-fed lots showed a gain.

In experiment 7 on rape pasture, a comparison was made between the effect of feeding with maize alone and self-fed maize and tankage given separately but in the same feeding. The pigs self-fed gained weight the most rapidly and at lower cost.

In experiment 7, on rape pasture, comparisons were made between full and limited supplementary rations. For the first 4 weeks, the ration consisted of middlings and tankage, ratio 14:1. This was followed by 17 weeks of hominy feed in place of middlings. For the pigs on full feed the average daily gain was 1.257 lb.; on approximately 2 lb. of concentrates daily per 100 lb. of live weight, 1.065 lb.; on an increased ration of 1

(1) See R. Sept. 1915, No. 942; R. July 1916, No. 780; R. Oct. 1916, No. 1103; R. July-Sept. No. 957; R. Oct.-Dec. 1919, No. 1197; R. Feb. 1920, No. 236; R. Nov.-Dec. 1920, No. 1175. (Ed.)

TABLE I. — *Comparison of Methods of Feeding Maize and Tankage to Pigs on Red Clover Pasture.*

Experiment	Method of feeding maize and tankage	Ratio of Maize to Tankage	Ration per 110 lbs weight	Initial weight per head	Length of test	Daily gain per head	Consumed per pound of gain		Gain accredited to an acre

(1) Not computed, as no check groups were fed in the dry lot.

to 3 lb. of concentrates daily per 100 lb. live weight, 0.721 lb.; on 1 lb. of concentrates per 100 lb. live weight, 0.428 lb. The control lot, not on pasture, *i. e.* the full feed dry lot, showed an average daily gain of 1.031 lb. The limited concentrated rations were of economic advantage, but the average weight of those slaughtered was less.

In experiment 9, a comparison was made between the full and limited feeding on soyabean pasture. The lots given maize alone, full-fed, showed an average daily gain of 1.029 lb. per head; as against 1.022 for those which received  $\frac{1}{2}$  of the full feed. The first lot consumed 4.348 lb. and the second 3.427 lb. of concentrates per 100 lb. weight. Another lot which was given a full feed + tankage, ratio 9 : 1, showed an average daily gain of 1.177 lb. per head, and consumed 4.238 lb. of concentrates daily per 100 lb. weight. Yet another lot received  $\frac{4}{5}$  of the preceding feed and showed an average daily gain of 1.004 lb. per head and consumed 3.605 lb. of concentrates daily per 100 lb. weight.

Still further experiments were made (Nos. 14, 15, 16) to compare the relative effects of pastures composed of various forage plants to ascertain the value of:— (1) field peas and oats; 2) peas and rape; 3) rape and oats; 4) oats and soybean; 5) rape alone. It was noted that the rape alone furnished green feed for a longer period than the mixtures.

In experiment 17 a comparison between sweet clover and soybean pasture showed that the pigs found the sweet clover unpalatable.

## POULTRY

194 - **First Egg-Laying Competition in France.** — *Revue de Zootechnie* (1) Year 1, No 1, pp. 85-87, figs. 2. Paris, October, 1921.

The first French Egg-laying Competition was held in 1920-1921, at Vaulx-de-Cernay.

The results were rather poor as was to be expected from hens which were mostly from poultry-yards where it had not been possible to select for egg-production.

The lots of fowls placed in the highest classes at the end of the competition were as follows.

*French Light Breeds.* — Lot No. 11 (6 hens) laid 632 eggs of the average

(1) The object of this Review, which is the organ of the French "Office d'Élevage" annexed to the national centre of Experimental Stock-Breeding at Vaulx-de-Cernay, is to form a link between: 1) French and foreign stock-breeding researches; 2) Scientific workers and stock-breeders; 3) Stockbreeders themselves; 4) French stockbreeders and their foreign customers. The Directors: M. DÉCHAMBRE, Professor of Zootechnology at the Ecole nationale d'Agriculture at Grignon, and the "Ecole nationale vétérinaire d'Alfort" and M. VOITELLIER, Professor of zootechnology, at the "Institut National Agronomique of Paris" described the programme (which includes amongst other subjects, summaries of the results of experiments; accounts of scientific researches; practical observations on animal production; bibliographical reviews, etc.), as follows: "An account of the work of the "Offices agricoles", reports of competitions and shows, the publication of the quotations of the chief markets with numerous illustrations explanatory of the text, together with information of a technical nature and useful suggestions as to the means of making stock-breeding in France profitable".

weight of 55 gm. The best hen in this class (a Gascon fowl), laid 186 eggs weighing on an average 54 gm.

*French Heavy Breeds.* — Lot No. 46 (Faverolles), laid 557 eggs weighing on an average 52 gm. The best hen of this class (a Gatinais bird), laid 142 eggs weighing on an average 58 gm.

*Foreign Light Breeds.* — Lot No. 79 (Ancona) laid 766 eggs weighing on an average 59 gm. The best layer in the whole competition belonged to this lot. It laid a total of 187 eggs (weighing on an average 59 gm), or more than 11 kg. of eggs.

*Foreign Heavy Breeds.* — The Buff Orpingtons laid 508 eggs. Average weight 61 gm. The hen placed first in this class belonged to this lot and laid 152 eggs each weighing 63 gm.

In comparing the results obtained for the different breeds as regards the French light breeds it was found that out of the 29 lots competing, only one gained more than 700 marks, 6 got over 600, 3 over 500 and 14 over 400. Out of 11 lots of French heavy breeds only one gained over 500 marks and 2 obtained more than 400.

Out of 16 lots of foreign light breeds 1 obtained over 800 marks; 2 over 700; 4 over 600; 5 over 500; and 4 over 400.

Finally, out of 4 lots of foreign heavy breeds, 1 lot gained over 600 marks and 1 over 500.

Thus the light breeds did better than the heavy.

195 - **Note on the South African Bee.** — SKAIFE, S. H., (Inspector of Technical Education) in *Journal of the Department of Agriculture (Journal of South Africa)*, Vol. II, No. 4, pp. 353-357, figs. 5. Pretoria, April, 1921.

BEE-KEEPING

The breeds of bees reared in Europe and America are rarely found in South Africa. Italian bees, which were at one time imported, do not seem to thrive.

The bees usually found in the hives have yellow bands, and belong to the *Apis adansonii* breed that is native to South Africa. *Apis unicolor* is chiefly met with in the Eastern districts; this bee is rarer, and less quiet than *Apis adansonii*, but an excellent worker.

Natural crosses between the two breeds appear to be of frequent occurrence, and in the same apiary workers of both types and intermediate forms produced by the same queen are often seen.

The pure *Apis adansonii* breed is well adapted to the conditions in South Africa; its characters vary considerably according to the different parts of the country.

As regards diseases, the European foulbrood, sacbrood (1) and paralysis have all been observed; American foulbrood has not yet been recorded. In order to prevent its introduction a law has been passed prohibiting the importation of bees, honey and wax (2).

(2) See R. Jan. 1912, No. 3. (Ed.)

196 — **Value of Formaline Vapour as a Disinfectant in Apiculture, Especially in Combating Foul Brood** (1). — BORCHERT, A., in *Berliner Tierärztliche Wochenschrift*, Year XXXIII, No. 46, pp 547-549, bibliography of 5 works Berlin, November, 1921.

The experiments made by the author for the purpose of determining the efficacy of formaline in the control of foul-brood have shown that the action of formaline vapour saturated with water vapour cannot be considered as satisfactory.

Honey-combs infected with the spores of bacteria and with micro-organisms in the vegetative state (*Bacillus alvei* Watson-Cheyne and Cheshire, *Bac. alvei* Krompecker, *Bac. megaterium*, *Bac. pyocyaneus* and *Bac. prodigius*), as well as cultures of bacteria in test-tubes were treated, but it was found that the formaline vapour only penetrates into small spaces with a narrow opening in such minute quantities that it was impossible to be sure of its destructive action.

Thus honey-combs infected with foul-brood cannot be rendered safe by the use of formaline, and treatment with formaline vapour cannot be substituted for MASSEN's method (2) which consists in destroying the pathogenic germs by melting the contaminated combs in a steam cerificator.

#### FISH BREEDING

197 — **Fresh Water Pisciculture in North Africa.** — RIVIÈRE, C. H., in *Revue Agricole de l'Afrique du Nord*, Year XIX, No 125, pp 931-934 Algiers, December, 1921

The species of fish found in the fresh or brackish waters of North Africa are few in number, and with 2 or 3 exceptions, of little importance from the point of view of food. Among the latter are the following:

1) A trout, *Salar macrostigma*, rare and only found in the mountainous region of Kabylia, Collo, Bougie and Babors, where the water is cold and clear owing to the altitude and the sheltering. This fish lives on rocky bottoms and dislikes mud, and at present has little value as an article of food.

2) The Eel, this fish, which is found frequently enough to be sometimes sold on the markets, is of good quality when taken from clear water, especially if it has abundant food. The author reared eels in the Experiment Garden at Algiers putting some of them into muddy water with little food, and others into clear water with a regular supply of food; he obtained heavier fish with better flesh by the latter method.

3) The Carp. This fish appears to have been imported to Constantine in 1857, when 40 young carp were sent with other fish by the Acclimatisation Society and put into the pond at Djebel-Ouach, where they multiplied. A certain number of Tench were introduced at the same time. Ten years later all the fish in the pond were caught: there were 307 carp from 18

(2) MASSEN, über die unter dem Namen "Paulbrut" bekannten seuchenhaften Brutkrankungen der Honigbiene, in *Mitteilungen aus des Kaiserlichen Biologischen Anstalt für Land- und Forstwirtschaft*, Heft 7, 2te Auflage, 1909

By the same author, Weitere Mitteilungen ueber Bienenkrankheiten und ihre Bekämpfung *Indem*, Heft 17, 1919 (Author's note)

to 45 centimetres long and 4 tench of 34 cm., as well as numerous fry of both species.

4) The Barbel, very common, two varieties being found: *Barbus cattensis* and *B. setifensis*. These fish are as a rule very thin, and more or less flavourless. They are very plentiful in the rivers of Morocco.

From the point of view of food value, none of the other species are of any importance, no matter what their surroundings may be. The Chromis is a fish with the flavour of the Perch, but it never attains a large size, and as it lives in the depths of the Sahara, could never be brought to market.

The following are all too small and too rare to have any culinary value: *Gobius*, *Cristiceps*, *Cyprinidon*, *Gasterosteus brachycentrus*, and *Tellia apoda*; the same remark applies also to the rather larger *Leuciscus callensis*, an insipid fish only found in the East of Algeria.

Some species seem to have been introduced with a view to acclimatisation in Algeria, this was probably the case with the *Carrassius* or Cyprin, which was found in certain rivers of West Algeria long before the French occupation.

Without any undue confidence in the future of pisciculture in North Africa which is poor in clear, deep waters of good quality, it might perhaps be worth while to make some experiments in breeding, were it only for the purpose of increasing even to a small extent the food supply of certain regions, especially of those at some distance from the sea. East Morocco, with its abundant supply of pure water, could provide by means of its reservoirs of irrigation water and its barrages, excellent fish-ponds situated at different altitudes, while some of the rivers and streams would become stocked by the fry that must necessarily escape from confinement.

Carp and tench could be reared in the quieter waters of the lower reaches of the rivers or in lakes and ponds, as long as care was taken to avoid those whose waters contain large quantities of sea-salt, or calcareous salts. Transport would not be an unsurmountable obstacle in the way of stocking the waters with these two Cyprinidae, for they are strong fish and travel well.

Suitable surroundings for trout are not so easy to find, and the species is more difficult to propagate, as fertilised eggs must be obtained for transport. Thus although the Kabyle trout would almost certainly become acclimatised in Morocco, to obtain and transport fertilised eggs would present serious difficulties.

In default of this species, it would seem advisable to introduce the fry of the Californian trout (*Salmo irideus*), as these have already been tried with success.

198 - Coccids of *Cottus Gobio* and of Carp Fry. — I. GAUTHIER, M., in *Comptes rendus de l'Académie des Sciences*, Vol. 175, No. 16, pp. 671-674, figs. 6. Paris, October 16, 1921. — II. LÉGER, L. and STANKOVITCH, *Ibidem*, No. 17, pp. 742-744. October 24, 1921.

I. The author's investigations were undertaken with the object of determining whether a connection exists between the Coccids of sea and fresh-water fish of the same family. He examined the "Miller's Thumb",

*Cottus gobio* L., a species which, so far as he knew, had never been recorded as suffering from these parasites.

The experiments carried out at the Grenoble Piscicultural Laboratory revealed the presence, in specimens of *C. gobio* from the basin of the Isère, of two species of tetrasporous coccidia (genus *Eimeria*), occurring either singly or together in the same host, but differing, from the type attacking the sea-form of *Cottus*. To the one species, which is characterised by its ovoid spores provided with a beak at one extremity, the author gave the name *Eimeria cotti*, the other which is a little larger and has ovoid biconical spores, alike at both poles, and often disposed in the form of a cross, he called *Eimeria piraudi*.

The author frequently found *Eimeria cotti* associated with *Eimeria piraudi* in the epithelium of the pyloric caecum and intestines of individuals of *C. gobi* coming from the Furon and the lower Isère. *Eimeria piraudi* had only been observed in the form of oocysts in the digestive tract of *Cottus* caught in the Isère in the neighbourhood of Grenoble. The oocysts are spherical, or slightly ovoid, and vary in size from 11 to 13  $\mu$ .

Of the two forms of *Cottus* coccidia, only *Eimeria cotti*, a specialised type with a tubular process at one pole, is entirely different from the other coccidia at present known to occur in fresh-water fish.

A study of the phylogeny of the 2 species shows that in all probability *E. cotti* is a primary parasite of *Cottus* whereas *E. piraudi*, an insignificant form of a type which is very common in fresh-water fish, would appear to be a secondary parasite connected with the adaptation of the genus *Cottus* to fresh-water conditions of life.

II. — In certain of the carp-breeding ponds of the South-East, the very young fry are often attacked by a coccid which completes its entire life-cycle within the epithelium of the intestine, where it multiplies to such an extent as to destroy the mucous membrane lining in some places, and cause a serious often fatal enteritis which greatly endanger the breeding prospects, for the fry that survive remain thin and weakly and their normal growth is arrested.

The authors describe the parasite, which is a new species, and suggest for it the name of *Eimeria carpelli* n. sp.

The fact that the same individuals harbour the parasite in all stages of development (the multiplication being both endogenous and exogenous), shows there is no intermediate host, the young fry becoming infected by the spores ejected into the water by diseased individuals. Hence the malady could be prevented by hatching and rearing the carp in ponds that have previously been drained dry.

The breeding-fish should be placed as late as possible in the pond, that is to say not before the temperature is suitable for egg laying and care must be taken to remove them as soon as possible after oviposition.

DUBISCH's method, which consists in frequently moving the fry from one pond to another (each pond having been previously kept dry until needed), has the additional advantage of providing the fish with surroundings entirely free from the germs of infection, and thus protecting them from the

intestinal forms of coccidiosis which, even when not fatal, hinder the growth of their hosts. In this manner, other factors being equal, the maximum quantitative and qualitative yield would be obtained.

## FARM ENGINEERING.

- 199 - **Harvesting Sugar Cane by Machinery Advantages of the "Luce Sugar Cane Harvester"**. — *The Louisiana Planter and Sugar Manufacturer*, Vol. LXVII, No. 25, pp. 396-398, pl. 4, diagr. 1. New Orleans, Dec. 17, 1921.

AGRICULTURAL  
MACHINERY  
AND  
IMPLEMENTS

Experiments with the LUCE sugar cane harvester were first started in 1900-1901 and have continued steadily for the last 20 years with a view to perfecting the present standard machine. The present model is now considered a practical, commercial machine, which will do the required work in such a way that the benefits derived from its use, all things considered, are sufficient, when represented in money values, to pay the interest charges or purchase price, the cost of working and the amortisation charges and still leave enough over to represent a fair net return on the initial investment.

Certain varying conditions encountered in different localities would affect the actual saving in cost per ton of cane harvested, *e. g.* the length of rows which has a direct bearing on the daily capacity of the harvester. The effect is shown graphically on the accompanying chart of curves. These curves also indicate the fact that the weight of cane per unit of area has also a direct bearing on the capacity and cost. For cane amounting to 20 tons per acre and in 1000 ft. rows, the capacity of the machine is approximately 16  $\frac{1}{4}$  tons per hour at cost of about 26 cents per ton. For this reason it is difficult to state exactly the cost per ton of cutting cane with this harvester, though it is evident that the cost is decidedly lower than with hand labour.

Another distinctly advantageous point lies in the fact that this machine gives a uniformly lower bottom cutting superior to that made by hand cutting, as the hand cutters invariably leave small stumps of cane in the fields. The bottom cutters of the LUCE harvester operate underneath the trash mat and cut the stalks off clean and square just at or below ground level. Besides leaving the stubble in excellent condition for the next crop, the yield is increased appreciably by the addition of from 2 to 4 in. of length to every stalk in the field. Careful experiments to determine the amount of the actual increase showed that the tonnage is increased by over 5 %. As this increase lies in the lower portion of the stalk, where the sucrose content per unit of weight is highest, the result is an increase in actual sugar yield per acre up about 8 %. It is estimated that the total amount of cane from a plantation, being say 25 000 tons from hand cutting, with a yield of 10 % would give 2 500 tons of sugar. With harvesters the increase in sugar yield (8 %) would be 200 tons. With sugar at 2  $\frac{1}{2}$  cents per lb. the actual money value of this increase of \$10 000.

Each stalk is handled individually and carried through the machine by steel conveyor chains, is topped at the last ripe joint, regardless of the

length of the stalk, and thoroughly stripped of leaves and trash before delivery at the rear. Delivery can be made direct into a trailer which dumps the cane in regular piles on the ground or is transferred to mill or cane hoist without entailing any hand labour . . .

The preparation of fields for the use of harvesters is neither expensive nor difficult, but necessary requisites are straight, long rows free from stumps and stones, while spacing should be sufficiently wide to avoid stooling entanglement with the machine, etc. Trash on the ground presents no difficulty, and may be as thick as 10-12 in. Leaning or blown cane is handled by these harvesters as effectively as clean, erect cane. The separator plough divides the row which is being worked from the one adjacent "and the pick-up fingers" lift the stalks to a substantially vertical position before the cutters reach the base.

200 - **Apple Packing Houses in the North Western Districts of the United States.** — PAILTHORP, P. R. (Investigator in Marketing of Fruits and Vegetables) and SAMSON, H. W., (Specialist in Standardisation), in *Farmer's Bulletin* No. 1204, United States Department of Agriculture, pp 3-39, figs. 26. Washington, D. C., June, 1921.

Description of the community packing houses, operated either by co-operative associations or by individuals in the apple-growing districts of the Northwest. The percentage of the crop packed in community houses is increasing steadily and estimates show that the amount increased from about  $\frac{1}{4}$  of the total crop in 1916 to approximately  $\frac{1}{2}$  of the crop in 1919. The same basic principles of construction and equipment are applicable to all types of houses and the equipment and methods of operation in the larger community houses are suitable to a large extent for use in the ranch houses.

This bulletin deals with the details of construction, arrangement, equipment and operations from the time of receiving the fruit for packing to their storage or putting on rail, and is based on a study of the methods and practices which have given the greatest satisfaction commercially. The figures illustrate the various points in construction including also grading belts, packing tables and stands, and suggested arrangements for gravity conveyors, elevators, chests, etc. An interesting packing floor plan shows the method employed in a well arranged community packing-house.

Fig. I here appended, shows the popular type of machine used for sizing boxed apples, and Fig. II, two types of lidding presses recommended.

The machines shewn in Fig. I, are 6 ft. 2 in. wide and vary from 30 to 52 ft. in length, depending upon the capacity. The smallest model is equipped with 8 bins and the largest with 48. They are provided either with a canvas sorting belt or with a roller sorting belt regulated by a lever operated by the head sorter. Opinions differ as to the relative merits of the two types of sorting belts. The sizing unit separates the fruit into 3 grades, each of which is delivered into a separate set of bins. The endless carrier

shown in the Fig. is composed of a series of cross rods carried forward by 2 side chains, and from these are swung canvas-bottomed carrying cups. The cups are held in a horizontal position by the supporting prongs which

*Apple Sorting Machine.*

FIG. 1. — EXPLANATION :

- A = Sizing apparatus.
- B = Sorting belt.
- C = The Shaker.
- D = Detachable plates for the belt.

slide along the iron side rails. Over each bin there is an opening in the side rails which is bridged by the inner bars of simple balancing scales. At the opposite end of the scale are canvas pockets into which the standard size

apples are placed. All that is necessary in order to make the machine ready to work is to place an apple of the desired size in the pocket of the scale, as the fruit delivered to the bin will correspond in size to the regulating apples. The cups of the carrier receive the apples, and as they move forward the supporting prongs at the sides of these cups pass in turn over the inner bar

FIG. 2 — Press for fixing the covers.

of each scale until one is reached which is counterbalanced by a regulating apple that is slightly lighter than the apple in the carrying cup. The inner bar of the scale is then depressed slightly, allowing the supporting prongs to pass through the opening in the side rail and causing the rear end of the carrying cup to lower gradually, thus delivering the fruit to the loops of webbing which are provided to break the fall of the fruit into the bin below.

With respect to Figs. II and III, the author states that a properly packed box should have a bulge of  $1\frac{1}{2}$  in. in the centre but tapering so that the apples in the ends are flush with the top. After lidding the bulge is distributed equally between the top and bottom.

FIG. 3 — Press for fixing the covers.

[200]

201 - **Flue-Curing Tobacco Barns and Packing House.** — JENNINGS, A. C. (Government Irrigation Engineer), in *The Rhodesia Agricultural Journal*, Vol XVIII, No. 5, pp. 529-533, Plans 3. Salisbury, October, 1921.

In consequence of the increased acreage under Virginian Tobacco and the possible need for more flue-curing barns, details of the most approved type of barns and packing house are here given, the plans and specifications given previously in the *Rhodesia Departmental Bulletin*, No. 334 dated Oct. 1919 being now cancelled. The accompanying drawings have been prepared under the advice of H. W. TAYLOR, Government Tobacco Expert.

The details given include specifications as to site, arrangement of buildings, foundations, walls, openings, roofs, furnaces and flues, ventilators and tiers.

As regards the packing house, the details specified for the barns may be applied, except where otherwise stated. A description is also added of the conditioning cellar built below ground-level under the packing house.

The plans illustrate 1) a block of flue-curing barns; 2) half elevation of back of barn; 3) half sectional elevation on centre line; 4) section through furnace, packing house, section elevations and plan.

A list is given of the materials required for a block of 4 drying barns (quantity, lengths or size. etc.), and also for the packing house.

## AGRICULTURAL INDUSTRIES.

INDUSTRIES  
DEPENDENT  
UPON ANIMAL  
PRODUCTS

202 - **The Practical Organisation of Milk Control in Belgium.** — *Bulletin de la Commission permanente du lait*, August-September 1921, pp. 70. Brussels.

The Permanent Milk Commission gives in this Bulletin a summary of the discussions that took place between the members of the Commission appointed to consider the question of the practical control of milk. At the meeting on July 7 1921, the following resolutions were unanimously passed by the members present.

"The Permanent Milk Commission after a through and careful study of the practical measures to be adopted for the organisation of milk control in order to insure the purity and hygienic condition of milk which plays so important a part in the preservation of public health, has come to the following conclusions:

1) It is most desirable that Public Administrations and Agricultural Societies should increase and encourage cow-shed competitions. It would be well to resume the keeping of Herdbooks.

2) All milk control should be founded upon the veterinary inspection of cowsheds and milch cows, in accordance with the royal decree based on the findings of the Permanent Milk Commission

The Permanent Milk Commission is further of opinion:

a) that with the assistance and under the supervision of the Public Authorities, a group of milk producers should be formed of which the members should voluntarily subject their cows and cowsheds to inspection. The milk of these cows should be tested from the hygienic, chemical and bacteriological standpoints. The producer of pure, wholesome milk should receive remuneration for this control, and this remuneration should be adequate and of a public character.

b) that the Governing bodies, both official and private, of hospitals, crèches and day-nurseries, etc., should forbid the use in their institutions of all untested milk, or of any milk coming from dairy-farms where the premises are not subjected at least to veterinary inspection.

c) that the above mentioned institutions should be provided with the plant necessary for keeping milk fresh and in good condition."

203 - **A Method for Detecting the Admixture of Goats' Milk to the Milk of Cows.** — AUSTEN, W., in *Deutsche Schlacht- und Viehhof Zeitung*, Year XX1, No. 25, p. 211. Berlin, 1921.

This method is based upon the fact that the casein of cow's milk is completely dissolved by ammonia, whereas the casein of goat's milk is insoluble in ammonia (1).

(1) See *R. March* 1916, No. 342. Another method has been described by A. GABOTHULER (*Zeitschrift für Untersuchung des Nahrungs- und Genussmittel*, Vol. 32, Part. 10, p. 453, Berlin, 1916). Goats' milk coagulates when subjected to the alcohol test, even if the degree of acidity is below 8. Milk with ordinary sediment and with a degree of acidity below 8, may be suspected of containing goat's milk if a precipitate is formed on the application of the alcohol test. The admixture of 30 % is easily detected. By a double alcohol test, the

This method does not give any practical values unless the milk is normal, that is to say, fresh. In order to keep milk fresh, bichromate of potassium is used instead of formaldehyde, which modifies the casein to the point of rendering it insoluble in ammonia, even after boiling.

The milk for the test should be as fresh as possible and free from all fat. The skimming is effected in the GERBER tubes generally used for determining the fat content, but they are closed at both ends with indiarubber stoppers. The fat that accumulated during centrifugation (temperature of milk 50° C) in the narrow portion of the GERBER tube is extracted by means of a glass tube attached to the sides. The 20 cc. of milk thus treated are heated in a water-bath at 50-60° C, then 2 cc. of 25 % ammonia are added and the mixture is kept at this temperature for half-an-hour, care being taken to shake it from time to time. The tubes are next placed in the centrifugator with the graduated part turned towards the periphery, and centrifugated for some minutes at the rate of 1200 revolutions per minute.

This method gives dependable results in the case of cow's milk which has been adulterated with goat's milk, provided 20 % of the latter is present: below 20 % the results are uncertain. As the qualitative test had given very good results, the author tried to apply it in determining the amount of goat's milk in the mixture. Cow's milk, with the addition of respectively 20 — 30 — 40 — 50 — 60 % of goat's milk, was skimmed, 2 cc.

addition of 10 % can be determined. With the alizarol test, woman's milk becomes violet, goat's milk brownish-yellow and cow's milk a lilac-red. In the reaction to neutral red suggested by MORO, woman's milk turns yellowish red, goat's milk orange, and cow's milk red. By their reaction in the presence of Nile blue sulphate, woman's milk (white) can be distinguished from cow's milk (blue) and goat's milk pale blue. With the ammonia test proposed by U. UMKOFF, woman's milk assumes a colour varying from pink to violet; the casein of goat's milk swells, whereas that of woman's milk and of cow's milk dissolves. In U. TUGENDREICH's nitrate of silver reaction, woman's milk becomes a coffee-brown without coagulating; goat's and cow's milk coagulate and the coagulum turns brown later. STEINEGGER's ammonia method combined with a centrifugal process makes it possible to detect even 3 parts of goat's milk in 100 parts of cow's milk.

There is on this subject another study by PRITZLER (*Ibidem*, p. 453-454). The method proposed by STEINEGGER (*Landwirtschaftliches Jahrbuch der Schweiz*, 1903, p. 233 and 1904, p. 221) has been modified by PRITZLER in so far that instead of reaction tubes, SCHMID's albuminometer is used. About 22 cc. of milk are centrifugated for 5 to 10 minutes at a velocity of 1400 revolutions per minute; the layer of fat is separated; 2 cc. of concentrated ammonia are added to the skimmed milk in the test tubes and the latter are shaken; they are then kept for half-an-hour in a water-bath at 45° C, and centrifugated for 3 minutes at 1400 revolutions per minute after which: in the case of pure goat's milk, there is a deposit of 8-12 cc.; in mixtures of equal parts of goat's and of sheep's milk, there is a deposit of 4-5 cc.; in a mixture containing 30 % of goat's milk, the deposit is about 3 cc.; when there is 20-15 %, the deposit is 2.1 cc. and with an admixture of 10-5 %, from 1 to 0.4 cc. Sometimes, no deposit is formed when the milk is 24 hours old, but coagulation takes place in the addition of 1/1000 of formaldehyde. Goat's milk, when treated with formaldehyde, behaves in the same manner whether 60 hours old or quite fresh. Cow's milk gives no precipitate after 60 hours on being treated with formaldehyde. (*Ed.*)

of 25 % ammonia added, and the mixture after heating in the water-bath was centrifugated for 10 minutes at a very high speed.

The precipitates in the GERBER tube were very well defined, and on being repeatedly measured, gave figures in the following table.

*Volume (in cc.) of the precipitate obtained in different milks.*

Proportion of goat's milk in the mixtures					Pure goat's milk
20 %	30 %	40 %	50 %	60 %	
0.6 cc.	1.2 cc.	1.6 cc.	2.0 cc.	—	5.6 cc.
0.6	1.1	1.6	2.1	3.1 cc.	5.5
—	1.0	1.4	2.0	—	5.5
0.5	0.9	1.5	2.2	—	—
—	1.0	1.6	2.3	3.2	6.2
0.4	—	2.0	—	3.1	—
—	1.4	—	—	3.2	—
0.5	—	—	2.2	—	—
—	0.9	1.7	2.3	3.3	—
<i>Averages</i> .0.5	1.1	1.6	2.1	3.1	5.7

Admixtures of 70 — 80 — 90 % of goat's milk gave very variable results. In mixtures containing from 20 to 50 % of goats' milk, every additional 10 % of goat's milk could be determined from an increase of about 0.6 cc. in the precipitate.

204 — **A Theoretical and Practical Study of the Ensilage of Forage Plants and of the Adaptation of the Process to the Requirement of Argentina.** — SCASSO, J. M., Ministerio de Agricultura, División de Investigaciones agrícolas y Estudios especiales *Ensilage*, p. 420, figs. 53. Buenos-Aires 1920.

This work, which is principally intended for practical stock-breeders, gives an exhaustive description of the different ways of ensilaging forages and the qualities of the silage obtained, particularly from the point of view of the special conditions of stock-breeding in Argentina. This is the criterion according to which the advantages and disadvantages of each type of silo in the different districts are discussed, the choice in each individual case being based upon local requirements.

The theoretical principles of ensilage are also stated, in order to serve as a guide for the handling of the forage treated. The practice of feeding stock on ensilage is taken into consideration and different rations and many subjects suitable for experiment are suggested. The economic factor receives due attention in a special chapter, and finally the author describes the plants most suited for ensilage, and studies their several possibilities, advantages and disadvantages.

The author especially recommends the use of ensilaged fodder in the feeding of young steers; he rates its value below that of fresh grass and above that of hay. Under the existing conditions in Argentina, more than 45

to 50% of the dry matter of grass is lost in hay-making, whereas under the most unfavourable circumstances not more than 25 % is lost during ensilage. Further, one ton of hay in the rick costs 6 to 7 pesos, but one ton of silage only costs from 2.7 to 3.7 pesos.

The plants most suited for ensilage in Argentina are lucerne, maize and sorghum. It would be worth trying in addition clovers, Hungarian "Moka", the "teosinte" (*Euchlaena luxurians*) and the sunflower. In districts where it flourishes, lucerne is always the best plant for ensilage (the native variety which is not infected with *Cuscuta* should be chosen); on clay soils, sulla can very well be planted instead of lucerne. Maize should only be given the preference where it is cultivated intensively, and already acclimatised varieties must be chosen such as "amarillo canario", "colorado de Baradero", "piamontés", etc. Recourse may be had to sorghum in the dry northern and western zones, where the best varieties appear to be the Sudanese, "Kafir Standard", and sugar sorghum. Wheat, barley and oats should only be ensilaged when drought or locusts threaten the grain production. Lucerne suits all types of silo, while maize is most adapted to cylindrical forms built above ground.

If lucerne and maize are ensilaged together, the most satisfactory proportions are 2 parts of lucerne to 1 of maize, i. it has not headed, or 10 of lucerne to one of maize, if bearing half-ripe cobs. Should the farmer have any molasses at his disposal, excellent results are obtained by ensilaging 15 parts of lucerne and 1 of molasses.

A perfect product results from the ensilage of unchopped lucerne. Maize can be put whole into the silo, though chopped maize gives better results, but it is expensive and works out to about 2 pesos per ton (1 paper peso = 2.20 fr. at par). Should a forage-chopper be bought for the purpose, one should be chosen with a large return and spiral rather than with flat blades. A forage-chopper cutting up one ton an hour requires a 23 HP engine.

Salt is not necessary, but if used, 1 kg. to 1.5 kg. is added per cubic metre.

The author reckons that after deducting the cultivation expenses of the lucerne and maize, plus the cost of cutting and transport to the silo, 1 ton of lucerne by the time it reaches the silo costs 1.40 pesos in Argentina; the cost of maize per ton being 2.59 pesos if cut by machine; 2.72 pesos if cut by hand and 1.74 pesos if cut by the maize reaper-and-binder. One ton of available forage (that is to say after deducting the losses sustained during ensilage), costs according to the silo used:

1) *pit silo*: lucerne: 3.68 pesos, if ensilaged unchopped; 5.46 pesos, if chopped; whole maize, 5.46-5.63 — 4.31 pesos, according to whether it is cut with a reaper, a hay-sickle or a binder-reaper; as for chopped maize, the first quality costs 6.86 pesos and the inferior quality, 5.85 pesos.

2) *Stack-silo covered with soil, or kept in position by weights*: cost of lucerne 2.69 pesos; of maize 4.34 pesos or 3.22 pesos, according to whether it is cut by a reaper, or a binder-reaper (for this type of silo, only unchopped forage is used);

3) a good-sized, wooden cylindrical silo constructed above ground : unchopped lucerne 7.01 pesos ; chopped lucerne 8.77 pesos ; chopped maize cut with a reaper 10.08 pesos, chopped maize cut with a binder-reaper 9.15 pesos (maize used in cylindrical silos above ground must always be chopped) ;

4) *Reinforced-concrete silo* : chopped or unchopped lucerne 6.53 or 4.77 pesos respectively : chopped maize 7.84, or 6.91 pesos, according to whether it was cut with a reaper, or with a binder-reaper ;

5) *Reinforced-masonry silo* : chopped or unchopped lucerne 6.31 or 4.55 pesos ; chopped maize 7.62, or 5.69 pesos, according to whether it was cut with a reaper, or a binder-reaper.

The most economical kind is unchopped lucerne silage made in a silo-stack. This type should always be made where extensive cultivation is practised.

Stock ought not to be exclusively fed on ensilaged forage as to give them nothing else is neither economical nor wholesome. In case of necessity, however, animals while being fattened may be given this food alone, if no hay or concentrates can be obtained. No better food exists for milch cows that are permanently housed than 15 to 20 kg. of ensilaged forage, per head and per day, with the addition of concentrates. If these consist of linseed cake mixed with grain, not more than 0.5 kg. per head and per day should be fed.

There is no proof that a diet of ensilaged forage causes abortion in females in an advanced stage of pregnancy. To prevent the milk acquiring the smell of the forage, all that is necessary is to remove the milk-pails from the shed as soon as the cows are milked.

The second part of the work contains the answers given by the different agriculturists to a form of questions distributed by the Division of Agricultural Research and of Special Studies of the Ministry of Agriculture of Argentina. It appears from the replies given that ensilage met with general approval wherever it was used.

205 - **Storage of Potatoes, Comparative Effects of Light and Darkness.** — MATRAS, A'. in *Journal d'Agriculture Pratique*, Year 85. Vol. II, No. 50, pp. 498-499. Paris, Dec. 17, 1921.

As a result of the statement made by NORFE to the effect that it is more advantageous to store potatoes in darkness than exposed to the light, conditions otherwise being equal, PAROW made comparative experiments with the object of elucidating this question. The details of his work are given in NAGEL's report in the *Zeitschrift für Spiritus-Industrie*, Berlin. The following résumé is here made by the author.

Two lots of potatoes, of absolutely identical character, weighing 5 kg. each, were placed in a cool (9° C) dry open spot on January 11, 1918 and allowed to remain there until July 22. One of these lots was placed in an open case and consequently was exposed to light, the other was placed in a closed case, i. e. in darkness.

The potatoes were weighed and analysed at the beginning and end of the experiment and from the reports made, the following results are distinctly worthy of note.

After 6 months storage	Open case	Closed case
	%	%
Loss on gross weight of tubers . . . . .	17.20	14.00
Loss of starchy content of potatoes . . . . .	21.86	15.25
Loss of sugar content of potatoes . . . . .	80.00	60.00

It is already recognised that the loss in dry matter from tubers stored in a cellar or silo from the beginning of the germination period (end of the winter) is greater than the loss resulting solely from respiration. On the contrary, light retards germination and may assist in restricting the loss of starch content which accompanies the process and results from the formation of diastases; darkness is on the other hand, useful previous to germination, that is to say, it acts only as a contradictory element as regards the losses provoked by respiratory phenomena.

Contradictory results have hitherto been obtained through not making a sufficiently clear distinction between diastatic and respiratory phenomena.

206 - **Transport of Market Produce by Aeroplane.** — JAUMAIN, E., in *Revue horticole belge*, Year 2, No. 12, pp. 169-170. Huy, Dec. 1, 1921.

The author states that where it is possible to utilise an aeroplane service for the carriage of produce as at London, Paris, Brussels, Amsterdam, this form of transport is superior to the railway for high priced flowers such as orchids, lilies, roses, etc. Although the cost of air transport is comparatively high, it is certain that the flowers will reach their destination fresh and undamaged and that consequently they, will fetch a higher price.

At the present time an air service for goods has been established between Brussels, Rotterdam, Amsterdam, Paris and London: the journey from Brussels to Rotterdam takes 1 hour 10 minutes; from Rotterdam to Amsterdam, 30 minutes; from Brussels to London, 3 hours 30 minutes.

## PLANT DISEASES

### DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

#### RESISTANT PLANTS

207 - **Forms of Hop Resistant to Mildew (*Sphaerotheca Stumuli*)** (1). — SALMON, F. S., in *The Annals of Applied Biology*, Vol. VIII, Nos. 3-4, pp. 146-163. Cambridge, Nov. 1921.

The wild hop (*Humulus Lupulus* L.) is composed of a number of forms which show distinctive physiological and constitutional characters.

One of these characters is the grade of susceptibility to the attack of the hop mildew (*Sphaerotheca Humuli*); these characters vary from extreme susceptibility shown both in the open and under greenhouse conditions, to a high degree of resistance in the open, and complete immunity in the greenhouse, with intermediate grades. Out of 291 ♀ seedlings examined, 165, or 56.70 % showed extreme susceptibility, while 18, or 6.19 % were "commercially resistant". The remainder fall into intermediate groups. Out of 480 seedlings, ♂ and ♀, 27, or 5.63 % were completely immune, and 7, or 1.46 % semi-immune under greenhouse conditions.

As a general rule, seedlings immune under greenhouse conditions conserve their high degree of resistance in the open.

208 - **Red Currant Varieties comparatively Resistant to American Gooseberry Mildew (*Sphaerotheca mors-uvae*) in England.** — SALMON, F. S., and WORMALL, H., in *The Gardener's Chronicle* (Third Series), Vol. LXX, No. 1804, p. 47, figs. 1. London, July 23, 1921.

In the fruit plantations at Wye College (Kent), in 1921, an unusually virulent outbreak of American Gooseberry Mildew (*Sphaerotheca mors-uvae*) on the gooseberry bushes (*Ribes Grossularia*) was followed by the appearance of this mildew on certain varieties of red currants (*R. rubrum*). In a border where Allington Pippin apples are interplanted with red currants, the young shoots of some of the currant bushes were seen on June 26 to be affected with mildew (*Sph. mors. uvae*). The effect was easily noticeable as the mildewed leaves curled somewhat so as to show the under surface on which large white, powdery patches of mildew were prominent. Further examination showed the presence of the brown, scurf-like patches of the perithecial stage of the mildew on the young stem and the young green berry.

(1) See also R. Febr. 1918, No. 232. (Ed.)

Investigation showed that only certain of the red currant bushes in this border were attacked. About 90 % of the border consisted of "Fay's Prolific", but the bushes attacked were clearly not of this variety, but rogues of various types, and some were probably "Raby Castle". The affected bushes were interplanted with "Fay's Prolific" which remained immune.

Another part of the same plantations gave equally convincing evidence of the resistance of "Fay's Prolific" to this mildew. A group of "Raby Castle" bushes were growing near a group of "Fay's Prolific". Here again all the "Fay's Prolific" bushes were quite free from attack, while the "Raby Castle" bushes immediately adjoining were badly affected.

The economic importance of the occurrence of the American Gooseberry Mildew in the red currant lies in the fact that the winter stage (carrying the winter spores or ascospores) occurs on the leaves, and is not confined as is usually the case with the gooseberry, to the stem. Where red currants adjoin (a gooseberry plantation, there is a danger of early outbreaks of this mildew on the latter, due to the presence in the soil of spores conveyed by red currant leaves. Affected shoots of red currant should be cut off and burnt before the leaves fall.

209 - **The Efficacy of Fungicidal Dusts for the Control of Wheat Smut (*Tilletia Tritici*)** (1). — MORETTINI, A., in *Le Stazioni sperimentali agrarie italiane*, Vol. LIV, Parts 7-10, pp. 293-315. Modena, 1921.

MEANS  
OF  
CONTROL

Prophylactic experiments against wheat smut (*Tilletia Tritici*) have been carried out since 1920 at the Casalina Agriculturists' Section of the "R. Istituto superiore agrario sperimentale" of Perugia. The object of these experiments was to test the efficacy of the time-honoured copper sulphate treatment as compared with the dry or powder method. In addition to the copper sulphate dust, "polvere Caffaro" was also used. The physical character and chemical composition of this powder seem likely to produce good results. By way of experiment the Caffaro powder was mixed with water in the proportions of 1 and  $\frac{1}{2}$  %. Its reaction being slightly acid renders superfluous the second lime-milk bath in the case of wheat seed that has been already treated by the fungicide. In the control copper-sulphate treatment, a  $\frac{1}{2}$  % solution of  $\text{Cu SO}_4$  was used. The grain was immersed for 15 minutes, and then immediately neutralised with milk of lime. After treatment the seeds were left to dry in the usual manner.

The powder treatment was carried out in glass balls with a capacity of 500 cc. in which the diseased wheat was placed together with the necessary amount of the fungicide and shaken for 3 or 4 minutes.

Both the copper carbonate dust and the "polvere Caffaro" were used in doses increasing from 2 to 15  $\frac{0}{100}$ . With 2  $\frac{0}{100}$  of copper carbonate there remained, after shaking for 3 to 4 minutes only slight traces of the

(1) See also R. April 1921, No. 419. (Ed.)

fungicide, but with larger amounts the residuum increased in proportion to the ‰, even after the seed had been repeatedly immersed. With "polvere Caffaro" the residuum exceeded 3 ‰. Although this powder is impalpable like the copper sulphate dust, it adheres much more closely to the seeds. Naturally the adherence of the two fungicides, when they are equally fine, depends upon the variety of wheat and its hygrometric condition. Some of the seed was treated 20 days before sowing, and the rest on the day it was put in the ground. A sample of each lot of seed was taken, in order to determine its germinating capacity immediately after treatment, and at the end of some months. The same measures were adopted in the case of the seed treated with copper sulphate and "polvere Caffaro" (after soaking in water), and the results of the two fungicides were compared.

The wheat used in every case was the hybrid Passerini which had been sorted by machine and contained some crushed and damaged seeds.

In the first series of experiments the wheat was thickly dusted with the spores of *Till. Tritici*, so that the whole mass was of a brownish colour. Practically it would be difficult, if not impossible, to meet with seed infected to this extent, for the mechanical processes of winnowing and sorting partially clean the caryopsids. The experiment was, however, useful from the research standpoint.

In a second series of experiments the wheat was infected with fewer spores and the conditions more nearly resembled those that actually exist under ordinary conditions.

The principal points to be determined were : 1) the effect of the fungicides upon the germinating capacity and energy of the seed ; 2) their effect upon wheat smut ; 3) their influence on yield.

The following conclusions were drawn from these experiments :

1) The usual treatment with  $\frac{1}{2}$  % copper sulphate which consisted in soaking the seeds in the solution for 15 minutes and removing the acidity of the copper sulphate by means of lime, has no perceptibly injurious effect upon germinating power or energy.

2) The application of powder, whether copper sulphate dust, or "polvere Caffaro") in the proportions of 2 to 6 ‰ had the same effect upon the germinating power of the wheat. Other factors being equal, the germination was improved.

3) In the case of wheat seeds that have been intentionally and excessively infected with the spores of *Till. tritici*, treatment for 15 minutes with a  $\frac{1}{2}$  % solution of copper sulphate is more efficacious in destroying the fungus, than the application of 2 — 4 — 6 ‰ of copper carbonate or "polvere Caffaro". The same applies to the strong doses, viz, those from 10 to 15 ‰.

4) On the other hand, where the wheat was less infected, though to a degree much exceeding any infection that could occur naturally, the dusting treatment is most efficacious ; 3 ‰ carbonate of copper having a greater effect on the fungus than spraying with copper sulphate, while 4 ‰ "polvere Caffaro" is slightly less efficacious.

5) "Polvere Caffaro" used in the proportion of 4 ‰ is a little less active than copper carbonate, but does all that is required.

6) Dusting, whether with copper carbonate, or "polvere Caffaro" is equally efficacious, if done on the day of sowing; it has no injurious action even if carried out eight months previously.

7) "Polvere Caffaro" mixed with water in the proportion of  $\frac{1}{2}$  % and applied for 15 minutes behaves like a similar solution of copper sulphate and renders superfluous any neutralising treatment with lime.

As regards the practical carrying out of the dusting treatment, whether copper sulphate or "polvere Caffaro" are used, the success achieved on a small scale by mixing the infected seed and the fungicide in little glass balls would seem to show that good results might be obtained with some adaptation of ordinary movable churns or similar apparatus, or even of simpler and cheaper appliances. The churn should be three-quarters filled with wheat and the fungicide, so that a few turns of the machine are enough to mix them thoroughly. Such an apparatus can be worked by machinery like the sorters used in the mechanical sorting of seeds. In the case of small quantities of wheat, use can be made of little barrels containing less than 1 hectolitre and with an opening allowing the wheat to be quickly introduced and removed. The wheat and the fungicide can be thoroughly mixed by simply rolling the barrel.

The author is, however, of opinion that further experiments are required, both for determining the efficacy of fungicidal dust in preventing the attacks of *Till. tritici*, and for testing the best apparatus for carrying out the treatment.

210 — **Stem-Rust Infection in Wheat in North-Dakota U. S.** — See No. 159 of this Review.

211 — ***Phyllosticta Montemartinii* n. sp., a Deuteromycete Injurious to the, *Loganiacea Buddleia variabilis*, in Italy.** — CIFEIRI, R., in *Rivista di Patologia vegetale*, Year XI, Nos. 9 and 10, pp. 114-115. Pavia, December 29, 1921.

DISEASES  
OF VARIOUS  
CROPS

In the neighbourhood of Macerata, three young specimens of *Buddleia variabilis* — a *Loganiacea* hitherto only grown in gardens as an ornamental shrub, but recently recommended for cultivation because of the signal service it renders to apiculture on account of its long flowering season and the wealth of its floral nectaries — were found at the beginning of the summer of 1921, to be suffering from fungus attack. Small, irregular patches of a yellowish-red colour and surrounded by a narrow whitish halo were observed on the leaves, and especially on their edges. Later, there appeared, on the infected part of the leaf-blade, the fructifications of a fungus regarded by the author as the pathogenetic agent described by him under the name of *Phyllosticta Montemartinii* n. sp. The diseased patches subsequently withered and became detached, leaving the leaf riddled with holes. At the end of the summer the leaves died and fell so that the shrubs became prematurely defoliated.

Spraying with Bordeaux mixture should be tried as a preventive and curative measure.

212 - *Fusarium cubense*, a Hyphomycete Injurious to the Banana in Porto Rico. — See No. 277 of this Review.

213 - *Colletotrichum Kaki* n. sp., a Deuteromycete Injurious to *Diospyros Kaki* var. *Kiombo*, in Italy. — MAFFEI L., in *Rivista di Patologia vegetale*, Year XI, Nos. 9 and 10, pp. 116-118. Pavia, December 29, 1921.

A specimen of *Diospyros Kaki* var. *Kiombo* growing in the Botanic Garden at Pavia has suffered since 1919 from a characteristic disease manifesting itself in the form of small patches nearly always occurring on the edges or at the tips of leaves, but occasionally found on the blade, whence they spread towards the centre and cover a great part of the surface of the leaf. The portion attacked withers and breaks, and finally the whole leaf falls. The spots which are of a more or less deep shade of hazel brown, are dotted about the healthy portion of the leaf, and stand out from the vivid green of its surface giving it a contorted warty appearance.

As the patches increase in size, they present concentric striae. In the end the spreading spots become confluent, affecting a large part of the blade and sometimes even covering it entirely.

Upon these affected patches on the upper surface of the leaf, numerous small pustules make their appearance, which when fully grown, are visible to the naked eye and are the fructifications of the pathogenetic fungus. The author speaks of the disease by the popular name of "macchie fogliari del kaki" (leaf-spots of the kaki), and describes the fungus as a species new to science, under the name of *Colletotrichum Kaki*.

214 - The Oak Oidium on the Chestnut Tree in Emilia, Italy (1). — MANARESI, A., in *Le Stazioni sperimentali agrarie italiane*, Vol. LIV, Parts 7-10, pp. 289-292. Modena, 1921.

During the second half of July 1921, many young chestnut seedlings, which had been sown the previous spring in the forest nursery of Bombiana, in the Commune of Gaggio Montano (Prov. of Bologna), were found to have their leaves, and also sometimes their stems attacked by a fungus that was identified as being without any doubt *Oidium quercinum* Thüm., a very common parasite of the oak, and occurring in the neighbourhood of the nursery on the young oak buds.

The presence of oak oidium on the chestnut tree had been reported in France in 1908, and observed in other parts of Italy besides Emilia, viz., in the vicinity of Savona, Prov. of Genoa (1909), near lake Nemi, Prov. of Rome (1915), as well as in the neighbourhood of Vittorio Veneto, Prov. of Treviso (1915), but in no previous case had young individuals been attacked.

In 1911, the parasite was again discovered on strongly growing chestnut cuttings at Zocca, Prov. of Modena, towards the end of August, and at Fontanelice, Prov. of Bologna, at the end of September.

(1) See also R. Feb. 1920, No. 264; R. Sept. 1920, No. 922; R. May 1921, No. 568. (Ed.)

According to the author, it is most probable that the parasite overwinters in the buds of the young host-plant, in which case it would be in a position when the spring came to infect the new shoots.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS

- 215 - **Artificial Production of "Tipburn" of Potatoes** (1). — FENTON, F. A., and RESSLER I. L., in *Science*, New Series, Vol. LV, No. 1411, p. 54. Utica, N. Y., Jan. 17, 1922.

GENERAL

Experiments conducted at the Iowa Experiment Station have shown that the Rhynchote *Empoasca mali* (potato leaf-hopper) is the factor concerned with the production of "tipburn" or "hopperburn" of the potato. Emulsions were made by crushing a large number of adults of both sexes in water and small quantities injected into the leaves of potato plants; in a few days the injury was apparent, similar to, if not identical with "tipburn." Difficulty was experienced in introducing large amounts of the emulsion into the leaf tissue, but enough was injected to induce the change. When the emulsion was placed on the leaf and the tissue pricked with a fine needle negative results were obtained. Emulsions made from crushed nymphs failed to cause damage except in a few cases, and even then it was not pronounced.

That these insects contain some toxic substance was further demonstrated by placing the residue left over from the insects after the emulsion had been poured off on leaf petioles and then inoculated by means of a fine scalpel. In every case a lesion was produced, the tissue at these points first turning yellow and then brown. Later the cells collapsed, leaving a fairly large scar.

Although Bordeaux mixture is toxic to the nymphs, it acts comparatively slowly so that by keeping a leaf sprayed with this compound colonised by live nymphs, "tipburn" was produced. This would appear to show that Bordeaux mixture does not prevent "tipburn" by its action on the leaf but rather by its action on the insect.

- 216 - ***Howardula benigna*, n. gen. and n. sp., a Nematode Parasite of *Diabrotica vittata*, *D. trivittata* and *D. 12-punctata*, in the United States.** — COBB, N. A., in *Science*, New Series, Vol. LV, No. 1409, pp. 667-670, figs. 4. Lancaster, Pa. December 30, 1921.

MEANS  
OF  
CONTROL

This article gives a description of the Nematode, *Howardula benigna* Cobb, n. gen. and n. sp. which is common in the body-cavity (abdomen, thorax and also the head) of the cucumber beetles *Diabrotica vittata*, *D. trivittata* and *D. 12-punctata*, especially the first. The nematode infests the two sexes of its host about equally.

The new parasite of *Diabrotica* spp. was first discovered at Marietta, Ohio, but subsequent study of its geographical distribution has shown that in 1921, it was probably co-extensive with the distribution of its main hosts *D. vittata* and *D. trivittata*.

(1) See R. July 1911, No. 2295. (Ed.)

About 1500 individuals of *D. vittata* were examined ; they came from different states of the North-American Confederation (Ohio, Illinois, Maryland, Michigan, Massachusetts, Virginia, Iowa, Mississippi, Montana, Texas, Minnesota, Louisiana, North Carolina, Connecticut, Alabama) and also from Canada (Nova Scotia and Ontario).

The nematism is often high and affects on an average 20 % (0 % — 70 %) of the beetles. The insects which come from a locality where they are not attacked by the Nematode are larger and more vigorous. Anatomical evidence shows the infested female beetles to be less fertile than the non-infested. In none of the numerous lots of beetles examined was the rate of infestation by any other animal-parasite as high as by *Howardula*, with the single exception of a 43 % dipterous infestation, but no note was made of degrees of phyto-infestation. As many as thirteen thousand Nematode larvae have been removed from the body-cavity of a single *Diabrotica vittata* and no doubt the number may go yet higher. On several occasions 20 or more adult specimens of *H. benigna* have been taken from a single beetle. Theoretically these should produce some forty thousand larvae or more. The older female beetles, when attacked by the Nematode, deposit a few to upwards of fifty of the nematode larvae with each egg. The grubs soon mature on the eggs or in the soil (where they can live several weeks), moult, develop a more perfect spear, and by its aid begin to make their way into the body-cavity of the beetle-larvae soon after the latter hatch out. It is rather improbable that the Nematodes enter their host by way of the mouth and alimentary canal.

217 — ***Oriolus luteolus*, A Bird Useful to Agriculture in India.** — FLETCHER, T. B. and INGLIS, C. M. in *The Agricultural Journal of India*, Vol. XVI, Part. 3, pp. 231-234, 1 coloured plate. Calcutta, 1921.

*Oriolus luteolus* (the Indian Black-Headed Oriole), has long been known in Indian ornithological literature under the name of *O. melanocephalus*.

In India it is strictly arboreal in its habits and rarely seen on the ground ; it lives chiefly on fruit and the small insects on the leaves and stems.

C. W. MASON examined the stomachs of twenty-three of these birds at Pusa, and found that seventeen of them had fed on wild fig fruits ; the stomachs of five contained nothing else. The stomachs of the 18 birds which had fed on insects contained ninety-five, of which four were classed as beneficial kinds, seventy-three as injurious, and eighteen as neutral. Five birds had eaten insects only. In the Central Provinces, E. A. D'ABREU found a Pyralid caterpillar and a *Ficus* fruit in the stomach of one Blackheaded Oriole on January 24, 1914. At Pusa, the authors watched the Oriole feeding on a mass of mealy-bug clustered on the stem of a wild vine growing on *Dalbergia Sissoo*. So far as agriculture is concerned, therefore, this bird may be considered as beneficial. *O. luteolus* has never

(1) See R. July 1911, No. 2295. (Ed)

been seen to attack cultivated fruits. This bird is protected throughout the year in Bombay, the United Provinces, Bihar and Orissa, Bengal, Assam, Burma, Madras and Mysore.

218 - **The Use of Crystalline Ferrocyanide of Potassium as an Insecticide** (1). —

RAYBAUD, I., in *Comptes rendus hebdomadaires de la Société de Biologie*, Vol. LXXXV, No. 33, pp. 935-937. Paris, 1921.

The author has investigated the effect produced upon the scale-insect *Ceroplastes rusci*, a common parasite of the fig-tree in Provence, by potassium ferro-cyanide applied for two consecutive years according to the method adopted in California since 1914 by SANFORD (2).

In February the author selected figtrees with a diameter at man's height from the ground, of 0.15 to 0.30 m., and made in their trunks a tubular cavity with a lumen of 0.01 to 0.03 m. and varying in depth from 0.06 m. to 0.15 m. In the case of some of the trees, the cavity was filled with the cyanide, in others it was left empty; the orifice however was always hermetically closed with a cork or wooden plug. A bluish liquid was seen to exude from the wound, when the cavity had been filled with ferro-cyanide, but not otherwise. Some of the branches of the trees containing the cyanide had been affected, and any leaves they already bore were destroyed a few days after the operation. The buds withered, and dried up completely, in the following year, while the branches themselves assumed the appearance of dead wood. Any scale-insects that still remained on them had also perished, though those on the other parts of the tree seemed in no wise affected. All the branches of the fig-trees in which the cavity was left empty were perfectly healthy. Thus the death of the branches was clearly due to the action of the potassium ferro-cyanide, and the trees appear to have reacted in some way to this toxic effect by producing the coloured liquid which exuded from the wounds.

The author then applied the same treatment to other species: *Pinus pinea*, *P. sylvestris* and privet (*Ligustrum*). These did not appear to suffer in any way though a very small quantity of the bluish liquid (resinous in the case of the conifers) was observed to flow from the wound. Two of the pines which were covered with caterpillars were not freed from these pests, and none of the insects were found dead near the tree trunks, although the last year the experiment was made just at the time the caterpillars appeared.

Without in any way casting doubts upon the results obtained by SANFORD who experimented upon other trees and other species of parasites, the author states that: 1) crystalline potassium ferro-cyanide is injurious when introduced into the trunk of the fig-tree; 2) *P. pinea*, *P. sylvestris* and privet all seem to resist its toxic action; 3) no toxic effect appeared to be exerted upon the caterpillars on the trees treated. Whether or not the scale-insects of the fig-tree were affected is a matter of

(1) See R. Feb. 1915, No. 235; R. Oct. 1915, No. 1103; R. May 1916, No. 596. (Ed.)

(2) See R. Feb. 1915, No. 235. (Ed.)

little importance, seeing that the parts of the tree where the scale-insects perished were themselves destroyed.

The author considers that the toxic effect of potassium ferro-cyanide is increased in the fig-tree by the presence of laticiferous tubes, which are absent in the trees which were able to resist the poison. He intends to make further experiments with the object of clearing up this point.

**219 - Experiments in the Control of the Olive-Fly (*Dacus Oleae*) by Means of the Lotrionte System of Traps ("capanette dachicide"), in Spain and Italy (1). —**

I. AGUILÓ Y GORSOT, J., in *Revista del Instituto Agrícola Catalán de San Isidro*, Year LXX, Part. II, pp. 213-215. Barcelona, Nov. 1921. — II. MARINUCCI, M., in *La Nuova Agricoltura del Lazio*, Year IX, No. 214, pp. 143-144. Rome, December 1, 1921.

I. — In 1921, the campaign against the Olive Fly (*Dacus oleae*), was carried out with great energy in the Province of Tarragona, Spain.

The control method preferred at Samá Park at Cambrils, was Lotrionte's "Capanette dachicide" system. These "Capanette" are small shelters made of tin, or preferably of galvanised iron, bent into one or two ridges, and containing a little bundle of twigs sprayed with a poisonous mixture. At Cambrils this method was adopted for two thousand olive trees, the roof of the trap being made of uralite.

A gang of workers was first of all formed to make the bundles of twigs and suspend them with wire beneath each "capanetta". By June 20, each tree was provided with a trap and the spraying with insecticide began.

In the formula used honey was an excellent substitute for molasses, no difference in the inherent value of the mixture being caused by the change. As the sweetening power of honey is greater than that of molasses, 14 % less of honey than molasses is required. The formula used at Samá Park was as follows: water 57 litres, honey 18 kg., borate of soda 1 kg., boric acid 1 kg., arsenate of soda 1 kg.

The insecticide is sprayed upon the twigs fixed to the trees beneath their "capanetta", by means of an ordinary knapsack-sprayer used for vines. A man can treat over two hundred trees per hour, and with 13 litres of the insecticide (the capacity of the sprayer) he sprays 215 "capanette", i. e. 215 trees. On the 8<sup>th</sup>, 18<sup>th</sup> and 20<sup>th</sup> of July, August and September the twigs were sprayed a second time; they were treated twice only in October, viz., on the 8<sup>th</sup> and 28<sup>th</sup>.

This experiment proved that the adoption of the Lotrionte method entirely protected the olive-trees of Samá Park from the attacks of the "fly". In point of fact, however, owing to the meteorological conditions obtaining in 1921, the season was not a favourable one for the increase of the parasite. Still, the Samá trees were free from attack, whereas those on other estates where the same system had been negligently carried out, or wholly omitted, suffered from the Olive-Fly to a small extent.

(1) See also R. July 1911, No. 2369; R. March 1913, No. 323. (Ed.)

The cost of spraying is as follows :

2000 "capannette" . . . . .	940 <i>pesetas</i>
affixing capannette to trees . . . . .	150 "
130 kg. of insecticide. . . . .	75 "
Wages paid for spraying . . . . .	15 "

The cost price of the substances used for the spray were : honey, 2 *pesetas* per kg., borate and arsenate of soda, 2.50 *pesetas* per kg., boric acid, 4.50 *pesetas* per kg.

As the "capannette" when once fixed on the trees, last for some years and the depreciation extends over five years, the cost per olive tree may be estimated at about 0.11 *pesetas* per annum. This also includes the cost of the wire used for suspending the traps from the trees. Thus in the case of 2000 olive-trees, the outlay according to the above figures, would be :

Depreciation of the "capannette" and wire and fixing of the same . . . . .	220 <i>pesetas</i>
1300 kg. of poison mixture . . . . .	750 "
Wages paid for control work . . . . .	150 "

The cost per 100 trees would thus be 56 *pesetas*, and if 20 % is subtracted for the increased price obtained for the fruit, the outlay per tree would be reduced to 45 *pesetas*, or 0.45 *pesetas* per tree.

The prices quoted above for the insecticide are a little higher than the normal ; it is clear, that, if the ingredients had been bought in large quantities by agricultural syndicates, or official institutions, and distributed to the agriculturists, the expense could have been reduced 20, or 25, %.

II. — Report on the results obtained in Italy in the control of the Olive fly by the Lotrionte method.

This work was begun in 1921 in the experimental olive yard of the "R. Scuola pratica d'agricoltura" of Rome (farm of S. Alessio in the Campagna Romana).

In 1921, Prof. Lotrionte wished to try a better poison mixture and also a new type of "capannetta" of a very simple kind, made of strands of reeds bound solidly together with string. The insecticide is directly applied to the inner surface of the bell-shaped "capannetta" to which it adheres better owing to the larger surface presented by the numerous projecting courses of the material. Such a "capannetta", which can last well for two years, is cheaper than the original type with a tin roof, and offers two distinct advantages : it does not get heated by the sun and thus provides a more agreeable refuge for the "fly" ; it excites less suspicion in the insects which alight even on the outside of the trap, for which reason the exterior also should be sprayed a little each time when the interior is treated.

These "capannette" are easily sprayed with an ordinary sprayer with intermittent action.

The insecticide remains in excellent condition for over twenty days on the surface of the "capannette", because it is very hygroscopic and

viscous, and contains no putrescent substances of which the odour would serve to repel instead of attracting the "fly".

The experiment was carried out on 700 average-sized trees (average diameter of foliage 5 m.), belonging to the College experimental oliveyard, and on 300 other trees in the neighbourhood, which were all that remained of olive-yards that were in course of being abandoned.

Only 700 "capannette" were used and none were affixed to small trees or specimens without fruit. Several control olive-yards were employed, these lay to the North-West, North-East and South-West respectively. The first (Lazio farm), contained a little over 200 trees, the second (Torlonia vineyard) had over 400, but both were about one kilometre from the experimental ground. The third, a larger oliveyard with over 1000 trees belonging to the Cecchignola farm, was about two kilometres distant. In the other directions there were no olive-trees within at least three kilometres. The zone treated was thus well isolated. The special Lotrionte mixture was applied four times to the "capannette" at the following periods: 1) June 30-July 2 (it took three days to attach the "capannetta" to each tree, for this was done by two of the college pupils during the afternoon hours set apart for field-work); 2) July 25-26; 3) September 12; 4) October 4-5.

Between the middle of July and the end of August, two sprayings of acid Bordeaux mixture were also given for the control of "Occhio di pavone dell'olivo" (*Cycloconium oleaginum*).

The insecticide used in this experiment was composed of: 50 % glucose; 2 % glycerine; 2 % boric acid; 2 % borate of soda; 2 % arsenite of potash; 2 % extract of Gorgonzola. Prof. LOTRIONTE is trying other less costly and more deadly formulae, and will make them known as soon as his researches and the experiments which he is carrying out are completed.

On November 10, a Commission was formed consisting of Professors B. GRASSI, Director of the Institute of Comparative Anatomy of the Royal University of Rome, and of the annexed Laboratory of Agricultural Entomology; A. MANGO, Royal Inspector of the Diseases of Plants, and M. MARINUCCI, in his two-fold capacity of Director of the "R. Scuola pratica d'agricoltura" of Rome and representative of the "Società nazionale degli olivicoltori".

According to the statements in the report of the Commissioners, the fruits of all the trees in the zone treated (experimental olive-yard), were fine and free from injury, except for the bruises caused by the hail of September 22. It is noticeable that this observation applied as much to olive-trees with large fruit containing a quantity of juicy pulp and to the "ros-ciola" variety, which has small olives that are soft and juicy, and hence very liable to the attacks of the "fly", like other varieties with average sized or small olives.

Samples were taken from many trees of different varieties growing in the zone treated and from these an average sample was made. This when examined on the spot, gave the following results: perfectly healthy olives

free from the "fly", 95 %; olives attacked by *Dacus oleae* 2 %. The Commission also noted that the pulp of the few olives attacked was as a rule but little affected, so that it could still yield much oil of a good quality. Few of the fruits had fallen, and even those on the ground were found to be free from the insect.

In the first control olive-yard visited (the Torlonia vineyard), the Commission immediately found the trees to be severely infested, especially those bearing large and medium-sized fruits, 90 to 100 % of which were attacked. From 30 to 40 % of the very small fruits of the "olivastri" (seedling trees that have not been grafted) harboured the pest, although they are usually left untouched or slightly injured, either because they gave little pulp, or on account of their late ripening. Samples were also taken from many varieties of trees in this control olive-yard, and an average sample made, which on being examined in Rome at Prof. GRASSI's laboratory, gave the following results: sound olives 23 %; olives attacked by the "fly" 77 %. The observations made in this oliveyard together with the results of the laboratory examination of the sample of olives gathered, showed that: 1) The few olives that were not attacked by the "fly" grew on "olivastri" and other kinds of olive-tree with small late-ripening fruits: 2) the infection in the case of trees with large and average fruits was never below 90 %; 3) the pulp of olives infested by *Dacus oleae* was, for the most part eaten away and much damaged, so that it yielded only a little oil of poor quality.

The sample of olives taken from the control olive-yard at the Lazio farm was examined by Prof. GRASSI with the following results: sound olives 1 %; olives attacked by the "fly", 99 %.

The olives gathered in the third control olive-yard (Cecchignola farm), were also found by Prof. GRASSI to be seriously attacked by the pest. No percentage was however calculated, as the crop was rather small and all produced by "olivastri".

The very high proportion of infected fruit on the Lazio farm is partly attributable to the small yield of the trees, which had borne a heavy crop the preceding year. The pulp of these olives was so much destroyed that only a little oil of bad quality could be obtained.

As a result of their observations and the data collected, the Commission concluded their report with the statement, that the experiment made in 1921 at the experiment olive-yard of the "R. Scuola pratica d'agricoltura" of Rome had been most successful and that without doubt the system of control adopted is as efficacious as it is practical.

220 - **The Potato-Tuber Moth (*Phthorimaea operculella*), in the Department of Hérault (1).** — LICHTENSTEIN, J., and GRASSE, P., in *Bulletin de la Société entomologique de France*, No. 18, pp. 267-268. Paris, 1921.

The author considers that the potato-tuber moth (*Phthorimaea operculella*, Zeller), found its way into Drôme and Hérault through consign-

INSECTS, ETC.  
INJURIOUS  
TO VARIOUS  
CROPS

(1) See also R. January 1920, Nos. 54 and 150; R. May 1920, No. 609; R. April 1921, No. 443. (Es.)

ments of infected potatoes. Potatoes containing the larvae of the moth were actually observed on the market at Montpellier, but the origin of the vegetable could not be exactly determined. Further, all the stored potatoes from a consignment coming from Montpellier itself were found to be infested. The moths were just emerging, for the authors saw some of them flying in the garden. Potatoes are not cultivated on an extensive scale in the district of Montpellier, but a certain number are grown by local gardeners, and large stocks coming from different regions are stored to supply the town. From the imported potatoes the moth could therefore easily penetrate into those parts of the Department where farm crops of these vegetables are raised. Hence, it is most important that its first appearance should at once be reported, and the infected tubers either destroyed, or covered with sand in order to prevent the emergence of the moth.

221 - *Ceroplastes* sp., a Scale-Insect Injurious to the Maté (*Ilex paraguariensis*), in the State of Paraná, Brazil. — Chacaras e Quintais, Year XII, Vol. XXV, No 6, pp. 467-468, fig. 1. São Paulo, December 15, 1921.

Among scale-insects lately reported as harmful, one new species has so far not been specifically determined: it belongs to the genus *Ceroplastes* and was discovered in the State of Paraná, where it attacks the maté (*Ilex paraguariensis*).

The branches and leaves of the host-plant assume a blackish colour, and the leaves, especially on their upper and the edges of their lower surfaces, are covered with black, apparently sooty, powder formed by the mycelium and fructifications of a Perisporiaceae (sooty mould), the growth of which is encouraged by the secretions of the scale-insects that adhere to the branches of the tree.

The following formulae are most commonly employed in the control of *Ceroplastes*:

1) black soap, 500 gm.; crude petroleum, 8 litres; water, 4 litres to be used for as a spray.

2) paraffin, 500 gm., vegetable oil of any kind, 800 gm.; ordinary soap, 1 kg.; water, 4 litres to be applied directly with a brush, or used as a spray.

Another treatment consists in cleaning the infected parts of the plant with soap, or tobacco extract, applied by means of a coconut brush or metal glove.

As the scale-insects increase with great rapidity, it is advisable to take the following precautions:

- 1) To keep the plantations as clean as possible;
- 2) To remove and burn all infected trees.

222 - *Lochmaea sanguinolenta*, a Coleopteron Injurious to the Melon in Catalonia, Spain. — AGUILÓ, J. in *Agricultura*, Year V, No. 15, pp. 354-355, fig. 1. Barcelona, 1921.

In September 1920, a whole crop of melons in the Province of Tarragona was completely destroyed by the Coleopteron, *Lochmaea sanguinolenta* Fabr., which had not previously been reported as injurious to *Cucumis Melo*.

The beetle devours the shoots and leaves of the plants while still quite young thus arresting the growth of the seedlings, which succumb to its persistent attacks. The few plants that survive are weakly and bear very few melons, which are of small size and acid flavour. *L. sanguinolenta* also frequently deposits its eggs on the leaves of its host, and as the larvae when hatched live entirely on the subterranean portions of the melon, the plants soon perish.

The following formula has proved efficacious in the control of the insect : 400 gm. of arsenate of sodium anhydride containing 60 % arsenic acid, 1 hectolitre of water, and 1 kg. slaked lime. Two sprayings at an interval of 5 or 6 days are sufficient.

223 - *Xylostodoris luteolus*, a Rhynchote Injurious to the Palm *Oreodoxa regia* in Florida. -- MOZNETTE, G. F., in *The Quarterly Bulletin of the State Plant Board of Florida*, Vol VI, No. 1, pp 10-15, pl. 3. Gainesville, Florida, October 1921.

The presence of a Rhynchote causing great injury to the palm *Oreodoxa regia* has been recently reported from South Florida. The insect was described for the first time in October 1920, under the name of *Xylostodoris luteolus* Barber, from specimens collected at Santiago de las Vegas (Cuba), where the pest also does great damage to the same palm.

In March 1920 the author received from Coconut Grove (Florida), portions of leaves of *O. regia* that had been seriously injured by an insect which he recognised as *Xyl. luteolus*. This is the first time that the rhynchote has been reported as occurring in the United States.

The insect attacks only the young and tenderest segments of the leaves of the top of the tree and of any rachis that is not unfurled. Since it shuns the light, it abandons the leaves as they begin to develop. A white spot forms on the leaf-segment attacked, after the puncture made by the Rhynchote in order to extract the plant juices upon which it lives. The spots increase in number and coalesce and the injured portion of each segment turns brown and dies.

The palm therefore soon assumes a very unsightly appearance.

After making many preliminary control experiments on small specimens of *O. regia*, living in the open and infested with the parasite, the author found that a mixture of one part of 40 % sulphate of nicotine in 1200 parts of water gave excellent results, for it killed the insect without doing any perceptible injury to the young growing tissues of the palm. Some fish-oil soap was added to this mixture (2 kg. being introduced into a receptacle having a capacity of 450 litres). A subsequent investigation of the palms that had been sprayed showed that 75 % of the insects succumbed to the first application. A second treatment was effected a week later which practically freed the palms from the insects, so that the trees began to put forth new, vigorous, healthy and handsome leaf-segments.

**The Mycoplasma Theory.  
Its Scientific Importance and Practical Significance.**

by

Prof. JAKOB ERIKSSON  
Stockholm.

A. — THE RUSTS OF CEREALS.

a) *The Usual Opinion as to their Origin and Propagation.*

The terrible injury caused by rust to the oat crop in Sweden in 1889, entailing a loss estimated at 16 million crowns, caused the Swedish Government in 1890 to allocate a special sum (10 000 crowns) for a further and thorough investigation of this disease. The work was entrusted to the Botanical Institute of the Royal Agricultural College at Experimental fältet near Stockholm. The experiments were to be carried on for three years under the direction of the author. Observations were made even during the preliminary investigations that were not in accordance with the generally-received opinion, according to which the origin and spread of the fungus are due solely to the spores of fungi (uredospores, teleutospores and aecidiospores), occurring in the neighbourhood. Moreover, these observations which were based on the facts mentioned later, proved without any doubt that these fungi existed under another evolutionary form.

Let us first recall the *studies made in the open* in wheat-fields, on grass land and in forests. The most striking results were obtained in the experiment field, in small plots, usually 3 m × 3 m, in which were grown year after year, many (300-400) varieties of rye, wheat, barley, oats and certain forage Gramineae, the seeds coming from different parts of Sweden and abroad. The growth of these plants was followed every year without

interruption and with the greatest attention from sowing to harvest. The *first appearance of the pustules* of the different forms of rust was especially noted and also the manner and *intensity of their development*. Every week or fortnight and in some cases every day, similar observations were made. These studies gave important and unexpected results. The date of the appearance of the pustules belonging to the same species of rust varied considerably with the different cereals, and often even on the several lines or kinds of the same cereal, and upon sowings made at different times, although the seedlings might be growing side by side. The difference in the time of the outbreak of the same type of rust, such as black rust (*Uredo graminis*), was especially striking in the autumn and spring-forms of the same cereal. e. g. wheat, although these varieties were only a few metres apart.

At the same time that these observations were being made in the experiment field, very extensive *infection experiments* were carried out in the greenhouse. It was found that when growing in the experiment field rye attacked by black rust was unable to transmit this disease to either wheat or oats, even if cultivated side by side with them. Thus the forms of black rust affecting various cereals would not appear to be absolutely the same. In the morphological species of *Puccinia graminis*, several biological races or specialised forms (*formae speciales*, f. sp.) are to be recognised; amongst these are found (in Sweden): 1) f. sp. *Secalis* on rye and barley as well as on certain other gramineae (*Triticum repens*, *Elymus arenarius*, etc.), 2) f. sp. *avenae*, on oats and some other gramineae (*Dactylis glomerata*, *Alopecurus pratensis*, etc.), and 3) f. sp. *Tritici*, on wheat and occasionally attacking very slightly rye, barley and oats. Mention cannot here be made of the specialised forms of certain species of the genera *Aira*, *Agrotis*, *Poa*, etc.

It must, however, be admitted that the infection cultures made in the greenhouse did not explain all the unexpected results obtained in the experiment field. This is especially the case as regards the *late appearance* in summer and autumn of the *primary pustules* of various kinds of rust. The first pustules of black rust are seen — not counting outbreaks occurring in the immediate neighbourhood on the barberry — on autumn cereals in the middle of July, that is to say at least 9 to 10 weeks after the thawing of the plants which have over-wintered, and a week to a fortnight later, on spring cereals viz., 10 weeks after sowing.

It was observed at the same time that the primary rust pustules only made their appearance at the moment when the growth of the host-plant was nearly finished.

The differences in the first appearance and the vital force of the same form of rust in different years, were also remarkable and not easy to explain. An attempt was made to account for then by the dissimilar meteorological conditions existing during these years, but without success.

The fact that in the case of certain forms of rust — for instance *Uredo glumarum* — the *uredospore production was enormous*, whereas the germinating and infecting capacity of these spores were as a rule very slight, capri-

cious, and without any apparent effect upon the spread of the disease, also remained an inexplicable phenomenon.

All these observations taken together led the author to look for another source of the appearance and propagation of the disease viz., a disease germ present in the plant itself.

b) *Latent and Plasmic Life of the Fungi.*

"Die Getreideroste" (Stockholm) was published in 1896 and contained all the chief results of the new experiments that had been obtained up to the summer of 1894. Throughout the book, runs like a red thread, the idea of an internal disease-germ inherited from the mother-plant and in many cases causing the outbreak of the disease. This view was stated publicly and definitely for the first time, at the Annual Meeting of the Agricultural Academy of Sweden, on January 28, 1897, and was repeated subsequently at the "Académie des Sciences" of Paris on March 1, and at the German Botanical Society at Berlin on the 24<sup>th</sup> the same month.

The author had sought in vain to prove by microscopic investigation the presence of those internal disease-germs. He certainly discovered in the peripheral tissue of wheat seeds that had been shrivelled and deformed by yellow rust, a well-developed mycelium and sometimes even clusters of winter spores, but all attempts to find a mycelium in the embryo itself while still enclosed within the seed, or in the seedling, continued fruitless. It was only towards the time when the spots of rust began to appear, 4-8 weeks after sowing, that a mycelium of this character was to be discovered, and even then, it occurred only in the immediate neighbourhood of the spots.

The author then put forward the bold hypothesis that the fungus had hitherto led a latent plasmatic life within the protoplasm of the host, living with it in a state of symbiosis to which the author gave the name of *Mycoplasma*. At a certain time and under the influence of external agents, these two intimately united plants separate, and an intercellular mycelium which produces visible pustules of rust soon makes its appearance.

In the work "*Sur l'origine et la propagation de la rouille des céréales par la semence*" (*Ann. Sc. Nat.*, Paris, Ser. 8, Vol. 14-15, 1900-1901), a large number of experiments in support of the new theory are described. The author, however, not being entirely satisfied with the results of the isolated cultures made from 1892 to 1898, of which a detailed account is given in the book, and realising that insurmountable difficulties might lie in the way of the solution of the problem by means of pure cultures made in special boxes and protected from external germs of disease, decided to employ the modern cytological methods of fixing, mounting and staining certain parts of the organs attacked. At this time the author had the good fortune to have as his collaborator G. FISCHLER, now professor of Botany at Hohenheim (Württemberg) with whom the experiments were carried out in common during 1902 and 1903, and later by the author alone. The results of these

investigations are published in the series "Über das vegetative Leben der Getreiderostpilze (I-IV *K. Vet. Ak. Handl. Stockholm*, 1904-1905).

From a minute examination of microtome sections of the leaves of autumn wheat, the pieces having been fixed and set in paraffin on October 6, 14 and 22, 1902, and April 22, May 29, June 5, 11 and 18, and July 4, 1903, it was again clearly shown that there was no trace of mycelium which could explain the reappearance of the disease the following year. Descriptions and drawings were given of the different phases of the evolution of the intracellular mycoplasma as well as of the course of the fungus in the intercellular spaces. The different stages of the evolution of the intercellular mycelium up to the eruption of the pustules, were also described and figured.

The author's theory did not, however, meet with approval, as can be readily understood, for the new doctrine was contrary to all the dogmas of the text-books, and to the opinions of every lecturer on the nature and propagation of cryptogamic diseases generally. The new views were regarded as heretical from the beginning, and they were to be combated by every means, legitimate or illegitimate. The author has replied in a series of publications to all the criticisms advanced up to 1911, and has now in the press a book answering the criticisms made in recent years.

#### B. — THE RUST OF THE MALVACEAE.

Amongst the best-known species of rust there is one nearly resembling the rust of cereals, the *Puccinia Malvacearum* Mont. (rust of Malvaceae). Its resemblance to the disease of cereals led the author to study this fungus and he has carried on his investigations from the beginning of the century *i. e.* for about 20 years. The results obtained during the first ten years are described in the book entitled "Der Malvenrost" (*K. Vet. Ak. Handl. Stockholm*, 1911), and he is about to publish shortly the results of the last ten years' experiments, in the work "Das Leben des Malvenrostpilzes (*Puccinia Malvacearum* Mont.) in und auf der Nahrpflanze (*K. L. A. Handl.*, Bd. 62, No. 5). These investigations have proved that this fungus also has a mycoplasma stage. The origin of this plasmas, that is to say, the entrance into the host-plant, has also been satisfactorily explained by these researches.

Proof has been given of the existence of *two forms of spores* similar from the morphological point of view, but *differing biologically*. One appeared *a)* on young plants of hollyhock that had just been raised *viz.* on plants in the autumn (September-October) of their first year, and *b)* on hollyhocks that had overwintered, *viz.* plants in the autumn (August to October) of their second year. These two forms of spores only occurred in hollyhocks belonging to a diseased line. The second form was called by the author *autumn spores*. The first appears some years in spring or summer, after a free interval of 3 to 6 weeks, in May and the last

week in July, on plants that have over-wintered. These are the *summer spores* (1).

*The autumn spores can germinate in two ways.* If they find themselves immersed in water, for instance at the bottom of a drop of water, they germinate by putting forth *long filaments* which are at first slender and straight (Fig. 1  $a_1 a_2$ ), and later become curved at the tip (fig. 1  $b_2$ ). The terminal, very short articulations break up and form conidia (fig. 1  $b_2$ ).

If, on the contrary, the spores are situated *on the surface of a drop of water, or in air saturated with water vapour* they germinate by emitting short, broad promycelia curved at first (fig. 2  $a$ ) and bearing sporidia (fig. 2  $b$ ).

The *summer spores* on the other hand, *always germinate* — in water or in damp air — *in the same manner, by putting forth long filaments and conidia.*

After inoculation, the *sporidia* send through the wall of the epidermis a vesicular filament giving rise to a mycelium in the tissues in the neighbourhood of the leaf, and after 10 days new spots of rust; the *conidia* discharge their contents in the form of a mass of plasm into cells of the epidermis in order as it would appear, to take entire possession of the leaf and there lead a mycoplasmatic life. After such an inoculation, no trace of rust pustules is visible for weeks.

In addition to *diseased lines* of hollyhock, there are also *healthy lines* that remain immune throughout the whole time of their growth. A healthy line can become infected if it comes up in spring or summer next to an infected one. A diseased line can however regain its health, if the vital energy of the fungus becomes exhausted.

### C. — POTATO MILDEW.

LIT. J. ERIKSSON, *Développement primaire du Mildiou (Phytophthora infestans) au cours de la végétation de la pomme de terre* — Rev. gener. de Bot. Vols. 29 and 30. Paris, 1917-1918.

Since *Phytophthora infestans* Mont. invaded Europe, in 1845, there has been an annoying hiatus in our information respecting the life cycle of this fungus. The overwintering of the parasite and its reappearance in the potato-fields the following year are facts that have not been explained. About 1875, a great discussion arose on these subjects among scientists. Some investigators believed they had found in certain diseased portions of the plant oospores (resting-spores) of which the function was to insure the continued life of the fungus. Others on the contrary denied this explanation and maintained that the oospores which had been found did not belong to this fungus but were those of another *Peronosporacea* belonging to the genus *Pythium*, their presence in the microscopic preparations being accidental. The German Professor, ANTON DE BARY, the

(1) Twice (1914 and 1916), the author observed that the production of autumn spores continued to the spring and throughout the summer of the following year.

most eminent mycologist of the day, was requested by the British Royal Agricultural Society to investigate the matter. In a work published in 1876, DE BARY pronounced in favour of the second opinion and his view was accepted almost universally.

It was clear that no light was thrown by this verdict on the re-appearance of the disease, but that on the contrary the solution of the problem was deferred until a distant future.

At the beginning of this century the study of the development of the disease entered on a new phase. In North America, and also in England, from 1904-1915, new and extensive researches were set on foot for the purpose of filling up the gaps that still existed in our knowledge of the disease, with a view to finding a better point of departure for its control. The chief method adopted in these experiments was the growing of pure cultures of the fungus from one year to the next on artificial media. In spite of every effort however the question of the over-wintering of the fungus still remained inexplicable.

In 1915, the author himself made this disease the object of the most careful researches. For the subject of his investigations he chose the spots of the primary disease (fig. 3), appearing in Sweden on the leaves of potatoes in the open field from the middle of July to the beginning of September, three or four months after the tubers had been planted. In 1905 and 1911, very small pieces of the rust spots and of the green tissue surrounding them as well of still healthy leaves, were fixed, embedded, cut and stained according to the ordinary cytological methods. The microscopic analysis of these preparations afforded very instructive results.

The first important discovery was of well-developed oospores (fig. 4b) in the withered or half-withered parts of the spots. These oospores were globular, 20 to 38  $\mu$  in diameter, and surrounded by a thick smooth membrane. They occurred either singly, or in groups of 2 or 3 in the remains of the spongy parenchyma of the leaf. Their formation is preceded by the fusion of a male organ (antheridium), and a female organ (oogonium) (fig. 4a). In sections containing these spores their germination could also be observed. These oospores germinate successively. They must not be regarded as resting spores, for they are on the contrary true summer-spores.

In germinating, the spore, which is either undivided or differentiated into several portions, puts forth through the neighbouring stoma, one or more slender processes (fig. 4c), which will form the aerial mycelium and have the method of branching characteristic of *Phytophthora*.

In order to learn the true manner in which the fungus overwinters, it was necessary to discover the origin of the primary mycelial filaments, and for this purpose to examine all the zones of the leaf spot. This investigation gave positive results. In certain cells of the peripheral zone of the spot, a characteristic structure of the protoplasmic mass differing from the normal structure of the plasma was found. By the help of a high power of magnification, this plasma was seen to contain numerous minute black dots dispersed amongst the chlorophyll granules. In other cells of the

various zones of the spot, and in the dark-green region surrounding it, all the successive metamorphoses of the plasmic body could be followed, from the disintegration of the chlorophyll granules and the appearance of the nucleoli, to the passage of the plasma through the cell membrane into the intercellular spaces of the tissue, there to form the primary mycelial filaments. Some of the branches of this mycelium form antheridia and others oogonia.

In the author's opinion, there is no doubt that two different organisms are present in this plasmatic mass (one forming part of the plasma of the host and the other that of the fungus), in a condition of intimate and latent symbiosis — the mycoplasma of the author.

By means of the researches just mentioned, the life-cycles of this fungus has been followed to its close.

It only remains to be discovered how the plasma enters into the mother-plant and lives there and whether a development more or less similar to that just described, but independent of it, takes place in the seed tubers during spring and summer. This is not improbable, seeing that the tuber is the organ by which the vitality, not only of the potato-plant, but also of the fungus parasitic upon it, is carried on from one year to the next.

#### D. — SPINACH MILDEW.

Lit J. ERIKSSON, *Zur Entwicklungsgeschichte des Spinatschimmels* (*Peronospora Spinaciae* [Grew] Laub) Ark f Bot Vol 15, Nr 5 Stockholm, 1918 — Compare also: Rev gener de Bot. Vol 32. Paris, 1920

The disease of the spinach (*Spinacia oleracea*) caused by *Peronospora Spinaciae* (Grew) Laub, has been known for over one hundred years. The spots of this malady appear some weeks after sowing and attain a fair size; they are irregularly distributed on the adult leaves. Their colour varies from white to yellow, and their lower surface is covered with a kind of bluish-grey felt. The spots spread rapidly, covering all the lower surface and killing the leaf.

The overwintering of this fungus is a much-discussed question, and many efforts at solution have been made without any satisfactory result. The authors' own observations, made during the course of many years upon the mode of appearance of the disease in different years, caused him to suspect that perhaps in this case also some plasmic symbiosis existed between the fungus and its host-plant.

During the summer of 1911, the author had the opportunity of making researches in this connection. At that time spinach was being grown at Experimentalfältet, Stockholm, on two small beds in the garden which were only 30 metres apart. Between these beds there were no trees or shrubs.

The first spots of mildew appeared on the plants of one of the beds on June 18, but the plants in the second were then apparently quite free from the disease. The author at once suspected that the plants belonged to two

different lines, the one diseased and the other healthy. On the same day pieces of leaves taken from the leaves of both beds, were fixed and embedded in paraffin.

The author's suspicions as to the health of the two kinds of spinach were found to be correct. After some weeks, all the plants of one bed were nearly dead, whereas the plants in the other remained free from disease until the seed ripened. Ripe seeds were collected from the healthy bed and sown the following spring in several different places. All the plants remained immune throughout the growth period. This admits of an easy explanation. The fact that the seeds of the two 1911 crops had been bought from different seed-merchants in Stockholm, would make it probable that they had different origins.

The microscopic investigation of preparations made from the two crops was very instructive.

In the first place it should be observed that there was not the slightest trace of mycelium to be discovered, either in the plants of the healthy line or in the apparently immune leaves taken from the diseased plants.

On examining the cell contents of the two lines however an essential difference was seen. *The cells of the healthy line presented a normal appearance (fig. 5 a. b.), their protoplasm being relatively clear and transparent. In the cells of the diseased line, on the contrary, the protoplasm was less clear and less transparent (fig. 5 c).*

By means of different staining methods and the use of the highest-power lenses, it was possible to distinguish in the cell content a *fluid colloidal substance in which were embedded small bodies in the form of granules or little rods (fig. 5 d),* resembling the Plastosomes, Mitochondriae, Microsomes, etc., of the zoologists. The chlorophyll granules of the diseased line differed also in their structure from those of the healthy plants, being less compact.

In the author's opinion, there is no doubt that the fluid colloidal substance with the granular and filamentous bodies it contains, is the *morphological system* of the stage of the disease to which he has given the name of *mycoplasma*. He was able to demonstrate the elemental structure of this stage of development for the first time by means of microphotography (2500).

I

The first sign of the disturbance of equilibrium between the substance of the fungus and that of the host-cell, is the more or less complete disintegration of the chlorophyll corpuscles, which is succeeded by the nucleoli stage. From this time the fungus may be regarded as the victor in the duel between it and the cell. Symbiosis has now given place to *antibiosis*. This might also be termed the *mycoblastema* phase (fig. 6 a), that is to say, the independent plasmic stage of the fungus. The latter, which has hitherto led an intracellular existence, is now ready to escape from its captivity and enter upon its own life as a parasitic filamentous fungus invading the intercellular spaces.

Occasionally, quite young fungus-processes are also to be seen in the preparations. Two such formations, one belonging to either cell are visible in fig. 6 b. These processes take the shape of short wide *plasmic tubes*. Since the processes of several cells fuse on meeting, it may be concluded that *these tubes are not surrounded* by a definite membrane but by a *thin film of plasm*. In figure 6 c, the processes of two neighbouring cells are seen fusing in this way, growth continuing afterwards in the same manner as in the case of a single tube.

Once it has penetrated into the intercellular space, the fungus tube gradually develops to its full extent, and *assumes the appearance of a thick mycelial filament*. As in *Phytophthora infestans*, antheridia and oogonia are formed. A fusion of the contents of the male and female elements takes place resulting in the formation of oospores. The latter germinate directly, the aerial mycelium passes through the opening of the stoma. This marks the close of the vegetative period of the fungus.

#### E. — IS THE MYCOPLASMIC CONDITION A FAIRLY COMMON FORM OF EXISTENCE AMONG PARASITIC FUNGI?

In the preceding observations, the author has given as concise an account as possible of his careful studies of the following diseases; Cereal rust (*Puccinia graminis*, etc.), Hollyhock rust (*Puccinia Malvacearum*), Potato mildew (*Phytophthora infestans*), and Spinach mildew (*Peronospora Spinaciae*). These studies have led him to suppose that there exist in these fungi a method of growth of a plasmic nature within the host-plant, *i. e.* a symbiosis between the plasm of the parasite, and that of the host-plant; to this symbiosis he gave the name of Mycoplasm.

It is natural to ask whether this mycoplasmic mode of existence is peculiar to the diseases mentioned above, or if it is of fairly common occurrence in the plant world. A decisive answer to this question would necessitate new and profound studies of many diseases which are not yet sufficiently well-known.

Basing his belief on the observations he has himself made for many years, the author is disposed to suspect the existence of a more or less protracted mycoplasmic condition of existence in the following fungi: *Puccinia Chrysanthemi*, *P. Ribis*, *P. suaveolens*, *P. Tragopogonis*, *Uromyces Betae*, *U. Alchemillae*, *Cronartium ribicola*, *Phragmidium Potentillae*, *Phr. subcorticium*, *Coleosporium Campanulae*, *C. Compositarum*, *Chrysomyxa Abietis*, *Melampsora salicina*, *Peronospora Ficariae*, *Sphaerotheca mors-uvae*, *Sph. pannosa*, *Microsphaera Euonymi*, *Rhizoctonia violacea*, *Plasmodiophora Brassicae*, *Colletotrichum Lindemuthianum* and also in Tobacco Mosaic, etc.

#### F. — THE MYCOPLASM THEORY AND ITS PRACTICAL BEARING.

If the parasite is so intimately associated with the host-plant, as the Mycoplasm theory would seem to indicate, might it not be possible to use the latter as the basis for the effective control of these diseases? Could

not the vital energy of the fungus element of the mycoplasma be destroyed, or at least diminished, without affecting that of the host-plant? This is one of the questions which any investigator must put to himself, if he desires to combat the plant diseases which are such a constant source of havoc.

The author hastens to add that in view of our present knowledge on the subject there is every hope that such results are attainable. In support of this theory he brings forward certain observations made on Hollyhock rust (*Puccinia Malvacearum*), the results of cultural experiments made in 1912 and 1913, in which an attempt was made to hinder, by the addition of a fungicide to the water when watering, the growth of the fungus element of the mycoplasma that was dormant within the hollyhock.

The experiments were carried out in zinc cylinders, of which 10 were used in 1912 and 8 in 1913. These cylinders were 3 m. deep and 0.62 m. in diameter; they were buried in the soil of the experiment garden.

A. — 1912 Experiments — On 3 May, 40 plants of hollyhock were dug up, and planted 4 in each cylinder. The plants belonged to a much infested line (rose de Chatel). The seeds had been sown in the summer of 1911. The young plants remained healthy until about August 15, but from the middle of September were badly attacked by rust. They were left in the open throughout the winter being merely covered with a layer of leaves and branches.

During the first 20 days the plants were given pure water as required. On May 23 the watering of the cylinders with a mixture of 1 % solution of copper sulphate began. The proportion of toxic salt was successively increased and in the case of certain cylinders reaches 10 parts per hundred.

On June 26, i. e. after 16 days, the first rust pustules made their appearance, although few in number, in eight cylinders. From this date all the leaves of the 40 plants were carefully examined and the extent of the disease in each case expressed as follows: 0 = absence of pustules, 1 = 10 pustules at most, 2 = up to 25 pustules, 3 = up to 100 pustules and 4 = over 100 pustules. At the same time, all the leaves were marked with spots of oil paint, so as to be recognised in subsequent examinations.

On comparing the plants in the cylinders during the course of the summer and autumn, a distinct difference was noted between those watered with water and fungicide solution respectively. On the first the amount of rust rose slowly at the beginning  $\frac{26}{6} - \frac{15}{7}$ , then rapidly increased

$\frac{15}{7} - \frac{22}{7}$ , reaching the third or fourth degree of the disease on a large number of leaves. In the cylinders treated with the toxic solution on the contrary, the degree of rust intensity decreased, first rapidly and later more slowly. No new pustules appeared and the old dead sori became surrounded with black circles (fig. 7 b) showing that the mycelial tissue round them was dead.

B. — *Experiment of 1913.* — On 2 May, 32 plants of the same line of hollyhock were replanted in 8 cylinders, 4 plants being put into each cylinder. The hollyhocks remained immune until May 24, on which day a very small number of sori were discovered on the leaves of three plants. Watering with a fungicide solution began on June 4. Two cylinders were watered with pure water, two with 1 per cent toxic solution, two with a 1 per cent toxic solution at first and subsequently with a 2 per cent, 4 per cent, and finally 5 per cent solution.

The results of the experiments are given in the following table :

*Immunisation Experiments carried out in 1913 at Experimentalfältet (Stockholm).*

Day	SERIES I: Pure water, 2 cylinders, 8 plants							SERIES II: Sulphate of copper (1 %) 2 cylinders, 8 plants						
	Number of leaves attacked by rust in degree					Dead leaves	Leaves total	Number of leaves attacked by rust in degree					Dead leaves	Leaves total
	0	1	2	3	4			0	1	2	3	4		
3.6	61	1	1	—	—	—	63	55	8	—	—	—	—	63
9 -	45	15	2	1	—	—	63	46	13	2	2	—	—	63

Day	SERIES III: Sulphate of copper (1.3 %) 2 cylinders, 8 plants							SERIES IV: Sulphate of copper (1.5 %) 2 cylinders, 8 plants						
	Number of leaves attacked by rust in degree					Dead leaves	Leaves total	Number of leaves attacked by rust in degree					Dead leaves	Leaves total
	0	1	2	3	4			0	1	2	3	4		
3.6	59	3	—	—	—	—	62	63	3	—	—	—	—	66
9 -	48	13	1	—	—	—	62	45	18	2	2	—	—	67
18 -	47	10	2	—	—	3	62	49	12	3	1	—	3	68
27 -	45	12	1	—	—	7	65	45	9	2	1	—	12	69
4.7	54	4	—	—	—	7	65	48	5	—	—	—	16	69
25 -	53	26	—	—	—	21	100	52	26	3	—	—	35	116

Four days later, on July 29, a very considerable change was noticed. The plants in all the cylinders were seen to be attacked by rust in the highest degree and remained in that condition until the end of the experiment.

In his long memoir the author proposes to give a detailed account of the results obtained during his last ten years' researches on the rust of the Malvaceae, so he is here only concerned with this remarkable difference in the appearance of the fungus.

The results described above clearly prove that it is possible, by the introduction of a fungicide solution, into the host-plant, to destroy or at all

*events to lessen the vitality of a fungus for a certain period of its life without in any way injuring the host-plant itself.*

A toxic solution can greatly reduce, at least for a certain time, the destructive energy of the parasitic fungus. This fact provides us with new and *efficative* weapons for combating plant diseases. It is true that so far the good effect of the substance used showed itself only during a certain period in the life of the fungus (June-July), and that this period was followed by another during which this favourable action was absent, so that the final result was not as satisfactory as might have been desired. All the same, however, *the discovery* must be regarded as *a great step forward*, and it must especially be noted, that the period in the life of the fungus when the efficacy of the fungicide was manifested, was the transmissible mycoplasmic stage of the parasite. The author sees in these results the prospect of successfully adopting a new kind of method in combating the diseases of cultivated plants. It is, however, certain that the theory of immunisation is not yet sufficiently advanced to be turned to practical account.

There still remains much to be done before such a treatment can be applied. In the case of a possible internal treatment, it would be necessary to experiment with different fungicides against various kinds of disease, and perhaps also to try therapeutic methods with serum, as adopted by doctors in the case of the diseases of man and the lower animals. In addition, it would be necessary, in given cases, to try external treatments with fungicide powders or solutions.

Naturally in such experiments there could be no question of watering entire fields, but only of treating a small number of plants of a certain kind raised in experiment gardens or green-houses, with the object of thus obtaining healthy seed.

For the carrying out of such experiments which are of paramount importance in order to increase the world's crops, the already-existing organisations — the Botanic Gardens of Universities and Agricultural Experiment Stations — are not sufficient, if it is desired to obtain, within reasonable time, results that can be turned to practical account. Certainly **it will be necessary to found one or more special International Institutes of phytopathological research** liberally provided with all the necessary equipment (laboratories, experiment fields etc.), where the most competent investigators of the various countries can carry on their researches. Such an Institute of Phytopathological Research could first be installed in Paris and annexed to the already existing Station of Plant Pathology.

## SECOND PART

### ABSTRACTS

## AGRICULTURAL INTELLIGENCE

### GENERAL INFORMATION.

- 225 - **The New Bureau of Agricultural Economics and the Scientific Work of the Department of Agriculture of the United States.** — WALLACE, H. C. (U. S. Secretary of Agriculture), in *Report of the Secretary of Agriculture*, 1921, pp. 16-27. Washington, 1921.

AGRICULTURAL  
DEVELOPMENT

The Secretary of Agriculture of the United States being convinced of the necessity for devoting as much attention to the economics of Agriculture as to the encouragement of production, if agricultural crises are to be avoided, decided after consulting expert opinion, to unite into a single Bureau (that of Agricultural Economics) the already-existing Bureaux of Crop Estimates, and of Markets and Farm Management and Economics and to concentrate in one bureau all the activities of the Department which are devoted to the economic aspect of Agriculture. The purpose of this new bureau is to enquire into every economic condition and tendency which affects either production or price, for the one depends upon the other.

The first questions to be studied will be farm management, types of farming, cost factors and market grades and practices, so far as they bear on the management of the farm, the cost of production and distribution being also considered at each stage. Investigations will also be made in land economics with a view to encouraging the most economical methods of working; land resources and the best means of utilising them; land settlement and colonisation; the marketing of farm products with a view to an improved organisation of distribution; market conditions; standardisation and grading of products; collection of statistics of production and distribution; crop and live-stock production in the United States and other countries; prices of farm manufactured products; historical and geographical studies in production and distribution with a view to interpreting the trend of agricultural prices and production; the development or decline of markets and the general geography of the world's agriculture; methods of finance; insurance of buildings, live-stock, and stocks in storage; taxation and its relation to production and distribution; the financing of

rural public utilities and other group enterprises ; agricultural conditions in countries which compete with the United States ; the characteristics and changes in rural home life and its relation to agriculture ; the trend of agriculture and population ; in short, everything that may assist the farmer along the path of scientific production. Such studies and investigation will be just as helpful to consumers as producers, for the ultimate purpose is to obtain an abundant supply of the products of the soil at prices which will support agriculture and be just to the consumer.

Much of this work is already in progress in the Department of Agriculture of the United States in accordance with the provisions of the organic law by which it was created in 1860. This department was charged with the duty of acquiring and diffusing "information on subjects connected with agriculture in the most general and comprehensive sense of that word."

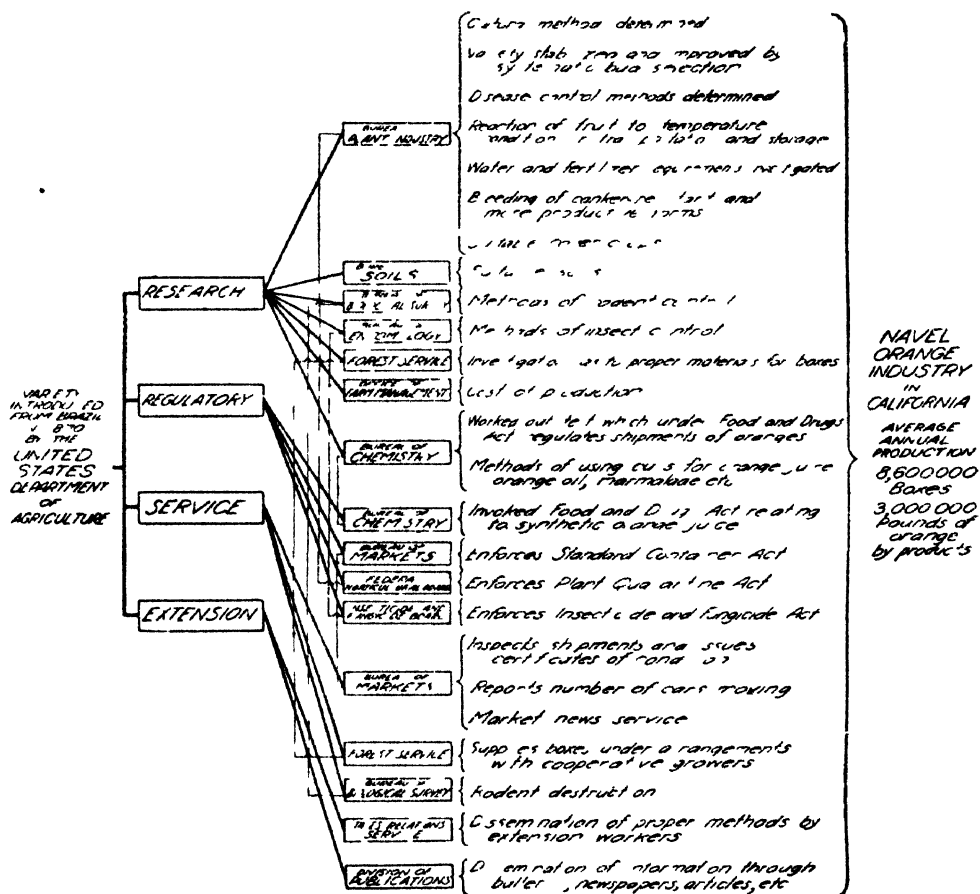

The production of food has long been considered as an obligation, but it is no less an obligation to bring it to the consumer with the least possible waste and expense. Marketing is as truly a part of production as crop-growing, for crops are of no value unless they can reach those who require them. The collection, storage and distribution of farm products require the same economic and technical knowledge as that needed by farmers. The acquisition and dissemination of knowledge of what to produce and how best to put it on the market so as to guarantee abundance of food at all times and at moderate prices cannot be gained from a study of marketing alone, but involve research in agronomic, biological, physical, statistical and economic science by men trained in their respective lines and having a working knowledge of agricultural processes and conditions. In fact the knowledge of what to produce involves study of the varieties, qualities and quantities demanded by the market. In the case of fruit for instance, it involves the selection or the breeding of suitable varieties by the horticulturist, a study of life processes by the plant physiologist, and the study of liability to attack by bacteria and fungi on the part of the plant pathologist. Practically all agricultural products are more or less perishable, and it is only by the co-operation of horticulturists, plant physiologists, phytopathologists, chemists, refrigeration experts and statisticians that it has been possible to give to American agriculture that distinctive character which makes it feasible to produce perishable commodities on one side of the continent and market them without serious deterioration on the other.

The accompanying chart showing the development of the Navel orange industry serves as a very good illustration.

In the marketing of grain, investigations are necessary on the milling and baking qualities of wheat and other grains, and for the purpose of determining the test weight per bushel, gluten content, colour, texture, general appearance, different forms of damage and adulteration to which grain is liable in handling. All this is necessary, not merely in order that the grain may be properly graded, but also that the most suitable kinds of grain may be bred, introduced and grown. This work has the profoundest

## DEVELOPMENT OF NAVEL ORANGE INDUSTRY

effect on farm operations. The cereal breeders in the Department, especially those engaged in the breeding of wheat, work with those engaged in the studies of grain markets and standards. The closest collaboration is also necessary between the specialists of the Department, who are familiar with varietal adaptation and the rapid changes taking place in the varieties grown by farmers, and those persons who have to do with the market, and particularly those concerned in formulating and administering grain standards. The rapid increase in the growth of red durum wheat made it necessary to introduce new standards for this class of wheat. Diseases play an important part in determining the market grade and value of cereals. The presence of smut for instance materially reduces the price of wheat and is always taken into account in grading. The shrivelling of wheat caused by rust and the presence of mouldy and rotten ears and spoiled kernels in maize due to rots and other fungoid diseases greatly affects their market value. Therefore the work of research specialists either in developing methods of controlling the disease, or in producing resistant varieties, is of importance not only to farmers, but to the grain trade and to consumers. It is necessary that the biological research workers should be in close touch with those who are studying grain-marketing and grain standards, so that the latter may be advised of outbreaks of new diseases or of the occurrence of already-known maladies. Crop rotation and farm management affect the purity of the products, and are therefore important factors in determining the grade of grain sold by the farmers. Practically every phase of research has its bearing upon marketing and benefits both producer and consumer.

Naturally, the basic work of the Department is in the field of research and it is upon the results of this work that its other activities are built. Of the 2500 different lines of investigation carried on in 1920, some of the most important may be mentioned : a new process for manufacturing phosphoric acid (without the immense waste in mining phosphates) and thus reducing the cost of fertilisers ; a method for separating the colloidal particles of the soil which is expected to throw light on such problems as cultivation of soils, the amount of water required by certain soils, their capacity for retaining plant foods and their reaction to lime ; the development of better methods for fixing atmospheric nitrogen for use as a fertiliser ; a soil survey that has completed the mapping of soils over an area of 1 063 588 square miles, including 31 915 square miles in Alaska and 300 square miles in Porto Rico, the work covering about 950 districts and 50 survey areas ; investigation of the rots of maize root, stalk and ear to determine the causes and methods of preventing these obscure and wide-spread diseases ; investigations of the effect of light and especially of the length of the day on plant development, furnishing explanations of phenomena in plant growth not previously understood but essential to accurate experimentation in the breeding of plants for economic purposes ; methods of accurate measurement of the productivity and other important characteristics of perennial plants, such as fruit trees, through bud selection which make it possible to replace undesirable trees by better types of the same va-

riety ; experiments for the purpose of improving the milking quality of cattle ; completion of the establishment of a breed of general utility fowls laying white eggs ; breeding experiments leading to the fixing of a type of American utility horse ; studies to ascertain the cost of producing various farm crops, and the cost of marketing ; studies to throw light on the whole marketing problem as a basis for the more efficient organisation of the various marketing processes, whether the work is carried out by individuals or by groups of farmers ; research to determine the composition of agricultural products in order to develop more uses for waste and surplus crops ; basic researches on the composition of foods and drugs in order to establish standards to prevent adulteration and to improve methods of manufacture ; research to develop methods of chemical analysis for the use of chemists in Agricultural Colleges, Experiment Stations and those connected with Federal, State, and Municipal food and drug departments ; the development of measures for the control of crop pests that have recently gained a foothold in the country ; researches to determine the characteristics of materials intended for highway construction ; researches to determine improved methods of highway design to meet modern traffic conditions ; studies of hydraulic problems, including the factors influencing the passage of water in drainage canals.

It is impossible to estimate the value of this research work, but the money spent on it is capital invested by the Nation in building up a permanent agriculture. Its dividends come from increase in yields, decrease in cost of production and marketing and better utilisation of crops, all having for their purpose the maintenance and increase of our food supply.

G. A. B.

AGRICULTURAL  
RESEARCH

226 - **The Present Position of Research in Agriculture in Great Britain and Suggestions as to the best Methods of Application to Practical Farming.** — I. HALL, Sir A. D. (Chief Scientific Adviser and Director General of Intelligence Department, Ministry of Agriculture), *The Present Position of Research in Agriculture*, in *Journal of the Royal Society of Arts*, Vol. LXIX No. 3567, pp. 300-312 London, April 1921 — II. VOELCKER, J. A., *How Best to Utilise the Results of Agricultural Research in Practical Farming*, in *Journal of the Farmer's Club*, Pt. 6, pp. 109-129. London, Nov. 1921.

I. — The organisation of research as applied to agriculture in Great Britain may be dated from 1909 when the Development Commission was established (1) and a scheme was formulated, dividing the field of research up by subjects and charging various Institutes with the fundamental research work for one particular branch, as a rule in conjunction with a University. This method was adopted in order to ensure concentration of effort, and to avoid overlapping and duplication and to give each Institute an opportunity to work out a continuous scheme of research and deal with the subject as a whole. Now that research is removed from immediate State control (apart from expenditure), the advantage of the association of the Research Institutes with the Universities has become evident, ensuring as it does informal co-operation with other workers in the

(1) See *R. May* 1913, No. 452. (Ed.)

field of pure science. Moreover the University which is teaching agriculture, comes into closer contact with the farmers in its district and much more so than a Government Department.

The Institutes that have already been established under the Scheme may be set out as follows :—

- 1) Soil and Nutrition of Plants, at Rothamsted Experiment Station, Harpenden (1).
- 2) Plant Pathology, at Rothamsted
- 3) Animal Nutrition, at Cambridge and Aberdeen Universities
- 4) Plant Breeding, at Cambridge and Aberystwyth (2).
- 5) Fruit Growing, at Long Ashton (Bristol) and East Malling (Kent)
- 6) Dairying, at Reading.
- 7) Plant Physiology, at the Imperial College of Science, London
- 8) Agricultural Economics, at Oxford.

The Plant Pathology Institute at Rothamsted represents a combination of previous Institutes dealing separately with entomology, mycology and helminthology. The Staff is kept in daily contact with the workers upon soil and plant problems

The two Institutes for Animal Nutrition are attacking different aspects of the same general problem. At Cambridge the Balfour Professor of Genetics receives a grant to carry out investigations into the laws of inheritance in animals which may prove of service in developing the science of breeding. The opinion is expressed that a wider scheme should be put forward dealing with Animal Husbandry as a whole including problems of a physiological character, etc

The Plant Breeding Institute at Cambridge deals chiefly with cereals and other farm crops, and the Aberystwyth Station (2) with grasses, clovers, oats and fodder crops appropriate to the wetter climate of the west. In order to relieve the Institutes thus engaged in the work of commercial distribution, the National Institute of Agricultural Botany has been set up at Cambridge to receive new varieties of farm crops from the Plant Breeding Institutes and to grow and test on a large scale before putting on the market in commercial forms.

The two Institutes dealing with fruit problems work in very close harmony and represent different conditions of soil and climate as regards fruit growing in the eastern and western counties respectively. A small Experiment Station at Waltham Cross (under the general supervision of Rothamsted) deals with the problems of the fruit and vegetable grower who works under glass.

The workers on Plant Physiology at the Imperial College of Science are associated with the Fruit Growing Stations for the purposes of obtaining material and for the conduct of the field experiments required.

Two subjects have up to the present not received sufficient attention.

(1) See « Book of Rothamsted Experiments » by Sir A. D. HALL (Second Edit. Revised by E. J. RUSSELL), Murray, Albemarle St., London, 1919

(2) See *R. Ang.* 1921, No. 808 (*E. d.*).

Firstly, diseases of animals :— It is considered desirable to set up an Institute for research into the comparative pathology of human beings and animals, with a view to obtaining results economically important both for the livestock industry and public health. Up till now the only work undertaken has been at the Research Laboratory at Addlestone, where certain questions specifically bearing upon the administrative work of the Ministry of Agriculture are investigated. A grant has also been made to the Royal Veterinary College for research work and recently to the London School of Tropical Medicine for investigations into the internal parasites of domestic animals.

Secondly research connected with agricultural machinery is of high importance. The future development of large scale agriculture depends greatly upon the application of machinery to farm work, and existing machinery probably requires certain radical modifications in view of the greater pace at which implements can now move because of the general introduction of mechanical power upon the land. Certain proposals in this direction are under consideration. The co-operation of the chief implement manufacturing firms must necessarily be assured.

*Advisory Officers.* — An essential feature of the Research scheme has been the further provision of a number of advisory officers attached to the various agricultural colleges, and relieved of their main teaching functions in order that they may give advice to farmers and horticulturists in their area, and conduct local investigations for their benefit. Eventually it is hoped to provide each college with 3 officers, as a rule a mycologist, an entomologist and a chemist, with modifications according to the special needs of the locality. Regular conferences are held between these officers, more especially the pathologists, directors of the related Institutes and the technical officers of the Ministry's Staff. In this way a systematic service is obtained to deal with plant pathology all over the country, which gives a general idea of prevailing conditions and furthers the possibility of a combined attack upon any disease of widespread distribution. At the same time these officers serve as intermediaries between the Research Institutes and the farming public, on the one hand disseminating the results of practical importance, and on the other, advising the Institutes on problems that have been revealed locally, which may prove to be beyond the resources of the individual adviser.

**MOST IMPORTANT PRACTICAL RESULTS WHICH HAVE ACCRUED FROM THE WORK OF THE VARIOUS INSTITUTES.** — I. *Soils and manures.* — 1) Rich cake-fed dung must be got early on to the land, if great losses of nitrogen are to be avoided.

2) The most essential feature in the treatment of the ordinary dung heap lies in protection from washing by rain.

3) If crude sewage (1) be passed through a filter bed made up of straw, the straw will pick the soluble nitrogen compounds out of the

(1) The Sewage Sludge as Manure. See R. Aug. 1915, No. 793; R. Sept. 1920, No. 843. (Ed.)

sewage in order to start the humification process. Some 60 % of the nitrogen is removed from the effluent which becomes comparatively harmless, and the straw itself is converted into manure.

These conclusions were drawn after a series of valuable investigations carried out on the bacterial processes which bring about the making of farmyard manure, based on the discovery of a widely distributed cellulose fermenting organism, a *Spirochaete*, (1) by HUTCHINSON.

Further trials are in progress to enable market gardeners, etc. to obtain effective farmyard manure without depending on animals, a necessary step due to the present diminution of town stable manure.

II. — *Plant breeding*. — Of special interest is the fact that wheats have been produced which under East Anglian condition have added 10 % to the farm yield (BIFFEN'S experiments at Cambridge). Some of these wheats combine the "strength" of Canadian wheats with the English cropping powers.

Experiments are in progress to solve the problem of lodging in cereals.

III. — *Animal nutrition*. — A set of real growth curves is being obtained showing for each stage of the animal's development the relation between the food consumed, the live and dead weight, the useful meat and fat and the offal. (Investigations at Cambridge).

Investigations (at Aberdeen) into the vitamine factor in the nutrition of farm stock are leading to valuable results.

IV. — *Fruit growing*. — The confusion which has arisen from a mixture of stocks upon which fruit trees are grafted, leading to lack of uniformity of habit, etc. is being gradually righted, and it is now possible to work with true stocks for apple trees.

Research is also in progress on fruit preservation.

V. — *Plant diseases*. — Immunity rather than curative methods is the chief aim; the success so far obtained is evident in the case of the wart disease of potatoes (*Synchytrium solani*), immune varieties which will grow untouched in the most heavily infected soils having been discovered. (2)

VI. — *Economic investigations*. — The Research Institute at Oxford has started to work out methods for ascertaining the cost of agricultural production.

Special emphasis is laid on the fact that the State is getting value for its expenditure and that the majority of really fruitful ideas and conceptions that have recently become current in agricultural science have sprung from English laboratories. Attention is drawn to the fact that Rothamsted is at present undoubtedly the most completely and efficiently equipped agricultural laboratory in the world, and while the other Institutes up till now are on the material side inferior to Rothamsted, they all display an activity of mind and a fertility of invention and method that can be matched in no other country.

(1) See *R.* July 1919, No. 820, and No. 236 of this Review (*Ed.*).

(2) See *R.* Feb. 1914, No. 182, *R.* May 1918, No. 519; *R.* April 1920, No. 420 (*Ed.*)

**EXPENDITURE.** — The total funds set aside in the current estimates for research service amounts to £105 000 as compared with £38 250 for 1913-14. It is interesting to observe the expenditure in the form of grants to Colleges and Institutions during the academic year ending September 20, 1920 :

<i>a</i> ) Scientific Research and Experiment :	£
1) Capital expenditure (Statement <i>A</i> ) . . . . .	28 588
2) Maintenance Expenditure (Statement <i>B</i> ) . . . . .	52 470
<i>b</i> ) Extension of Advisory and Local Investigation Work (Statement <i>C</i> )	13 798
<i>c</i> ) Special investigations and researches not included above* (Statement <i>D</i> ) . . . . .	2 028
Experiments with Agricultural Machinery ** . . . . .	4 000
Miscellaneous Enquiries, experiments, etc. . . . .	1 500
Research scholarships **. . . . .	1 900
	101 284

\* Grants made to individuals in furtherance of approved schemes of investigation, intended for the benefit of teachers, etc in Agricultural Colleges, Universities, etc. other than Research Institutes.

\*\* Financial year ended March 31, 1921, estimated.

Details are given of the amount paid out under headings *a*, and *b c*.

It may be noted that the greater part of the expenditure goes upon the salaries of research workers and the State undertakes to provide the salaries with certain increments for a defined number of officers. This step has been taken in order to ensure that the general conditions are suitable for the highly trained University graduates who are best fitted for research work. The system of scholarships permits promising students to engage in research under the guidance of an Institute with a view to possible promotion.

**II. — UTILISATION OF RESULTS OF RESEARCH IN PRACTICAL FARMING.** — Dr. VOELCKER testifies to the value of the Universities, Colleges and Experiment Stations as sources of information, but devotes special attention to the methods so far adopted and others that might be employed for bringing the farmer into direct contact with these scientific teachings, always bearing in mind the somewhat conservative attitude of the farmer class with regard to science.

*a*) *Value of Agricultural Publications.* — These have accomplished a good deal, but seeing that the ordinary agriculturist is not a great reader and that many of the agricultural monographs bearing on practical problems are not readily understood by the farmer, it is considered advisable to introduce science into the ordinary school curriculum as soon as possible and thus pave the way to a clearer understanding.

*b*) *Value of Experimental Work.* — The importance of each station keeping in close touch with all other stations at home and abroad is emphasised (1) but the chief aim should be to give a clear interpretation of the

(1) " On the Continent, through the United States and Canada, also at centres in India and elsewhere, there are experimental and research stations each issuing regularly its report of work and in turn, keeping in touch with Rothamsted and other Stations. The work of

scientific discoveries and their practical bearing in order to allow the farm student to have a thorough grasp of the situation. Where practical experiments have been carried out on experimental farms run in conjunction with the various Colleges, and these have been made readily accessible to the farmer, distinct progress has been made.

c) *Agricultural Colleges and Farm Institutes*. — Apart from the Research stations mentioned elsewhere, opportunities for complete training in agricultural science are given to students and young farmers and in many cases provision is made for carrying on experiments on individual farms in the surrounding area. Among the best-known colleges are Armstrong College (Newcastle-on-Tyne), Leeds University, Harper Adams College (Salop), Midland Dairy and Agricultural College (Loughborough), the University Colleges of Aberystwyth, Bangor and Reading, and Wye College (Kent).

In addition to the more scientific instruction, there is a group of lower grade Institutes and Farm schools attended by persons who can only give part time to learning and are otherwise engaged in actual farm work. Here demonstration farms take the place of experimental farms, and a general teacher of science replaces specialised teachers of particular branches. The best known at present are the East Anglian Institute at Chelmsford (Essex), Marton (Rugby), Newton Rigg (Penrith), Sparsholt (Winchester) and Usk (Monmouth).

d) *Agricultural Organisers*. — The value of the services of the itinerant lecturer and advisor is fully acknowledged (see Pt. 1).

From the results obtained up to the present it appears that before long a practical knowledge of the application of scientific discovery will be much more readily acquired to the ultimate benefit of agricultural progress.

M. L. V.

227 - **Report of the "Imperial Economic Botanist" Pusa, India 1920-1921 with Reference to Wheat, Tobacco, Fibre Plants, Oil Seeds, Grain, and Indigo, including Physiological Investigations.** - HOWARD, A., and HOWARD, G. I. C., in *Scientific Reports of the Agricultural Research Institute, Pusa, 1920-1921*, pp. 8-20, p. 11, bibliography of 7 works, Calcutta, 1921.

WHEAT. — The demand for botanically pure seed of Pusa wheats for trial in various parts of India including the Indian States, for starting new centres of seed distribution and for restocking old ones has been continuous. Special demands were made for Pusa 12 and Pusa 4 and a record has been kept of the progress made in the systematic replacement of the country wheats by these two varieties and in the first area selected, viz. the Central Circle of the United Provinces, it was decided to aim at the complete replacement of the country wheats of the alluvium, by Pusa 12 and in the district of the Bundelkhand canals by Pusa 4 and to base the various distribution schemes on the central seed farm at Kalian-

these stations is regularly summarised in the "International Review of the Science and Practice of Agriculture" published by the International Institute of Agriculture, Rome. (*Author's note*)

pur (1). The aims and objects of the work and the progress made are expressed in concrete form, and a description is also given of the various unofficial methods of seed distribution which have been tried by the Agricultural Department.

The chief aim of the work done taken as a whole was to establish a definite co-operative movement for the distribution of the improved seed and the consequent introduction of varieties superior to the local types hitherto cultivated. To attain this end, side by side with the various seed distributing agencies, the Agricultural Department has conducted a continuous series of village demonstrations.

The importance of strength of straw in wheat cultivation is well brought out in some wheat trials carried out by W. N. HARVEY at Gorakhpur. Plots of Pusa 4 and the local wheat, 0.24 acres in area were sown in triplicate and the wheat was irrigated once. In spite of wind and rain in January which laid the local variety, Pusa 4 stood well till harvest and gave a yield of 29.50 maunds of seed per acre (1 maund = 82.28 lb.). The sparse foliage of Pusa 4 combined with the natural strength of its straw and its short growing period combine to make it a suitable variety for trials in intensive cultivation. A yield of as much as 40.75 maunds per acre has already been obtained on the large scale at Mangalghar (Bihar) under estate conditions.

One of the limiting factors in the growth of wheat in India is soil-temperature. It has however been reported by S. K. BASU, Deputy Director in Orissa, that varieties which mature with great rapidity, and require a short growth period can be matured in tracts where the cold season is too short for the ordinary crop. He recently raised a crop of Pusa 4 of over 18 maunds per acre on the rice areas in which the paddy crops had been destroyed by high floods the preceding July. The wheat was sown the first week in November and harvested early in March. These trials are being extended in new tracts.

With reference to water saving in wheat cultivation, the results obtained in North-West India are notified in *Bulletin 118 of the Agricultural Institute of Pusa* (reproduced from *Quetta Bulletin* No. 4).

*Trials of the New Pusa Wheats.* — One of the objects of this work is to obtain a bearded wheat with strong straw which will yield as well as Pusa 12 under cultivator's conditions. Pusa 54, giving an average yield per acre of 32 maunds, 34 seers and other types not yet tested at Kalianpur appear promising for this purpose, (when compared) with the average yield of Pusa 12, viz. 33 maunds, 8 seers.

Some of the Pusa wheats have evidently been found useful in breeding elsewhere. Prof. SCHRIBAU of the Institut National Agronomique, Paris reported in June 1921 that by crossing the rust resistant Pusa 4 with Bordeaux, the hybrids obtained were clearly resistant to rust.

TOBACCO. — There has been an increased demand for type 28 from

(1) The present position of the work has been summed up in the *Agricultural Research Institute, Pusa, Bulletin* No. 122, by BURT, B. C., HOWARD, I. A., and HOWARD, G. L. C. (Ed)

the Indian Leaf Tobacco Development Company and successful trials have been conducted recently at Guntur in the Kistna delta in accordance with the local demand for seed. In these experiments about 97 % of the plants lived when transplanted and gave a tobacco of very good colour, useful for cigarette manufacture. The Company is also undertaking trials of this variety in British East Africa, Kenya and Zanzibar. After providing for 50 000 acres this year, sufficient seed for 60 000 acres has been carried over for 1922 but the advance indents have already reached this figure.

**FIBRE PLANTS.** — A successful trial of the improved variety of "patwa" (*Hibiscus cannabinus*) (1) known as type 3 is reported by the South African Jute Company, Barberton, South Africa; the plants withstood drought, gave stems 10-14 ft. high, and a yield of fibre 35 maunds per acre on land freshly broken. (These trials are being continued on a larger scale). Type 3 has as a result been given a trial at Pusa and elsewhere, but only a small supply of pure seed has been so far maintained. It is expected shortly to be able to prevent natural crossing more easily and thus enable the extension of the crop areas.

Breeding work on roselle (*H. Sabdariffa* L.) discontinued in 1919 and 1920, has since been resumed.

**OIL SEEDS.** — Considerable progress has been made in the isolation and study of the unit species which make up the Indian linseed crop of commerce. Results are awaiting publication when the types have been repeated for detailed verification of the classification. The testing of some of the unit species has been started and is yielding promising results.

An exhaustive examination has been made in Great Britain of the commercial possibilities of safflower (*Carthamus* spp.) oil. The work has been carried out by S. S. REMINGTON at Aynsome, Grange-over-Sands, Lancashire who reports on its distinct economic value for colour, paint and varnish industries, for soap and linoleum manufacture, as well as for edible purposes and its possibilities for refining and bleaching. Further investigations are in progress on the proteins of the safflower seed and it is considered advisable to test the changes taking place in the oil under ozonisation, further weathering tests, etc.

**GRAIN.** — Some progress has been made in the testing of a number of promising types of grain. Large scale trials have been in hand with Pusa 17 and Pusa 18 which gave 21 and 22 maunds of grain per acre respectively. These trials were, however, interfered with by premature hot winds when the plants were in flower.

**INDIGO.** — Apart from the several publications issued recently on this subject (2) it is interesting to note that the authors' views on the impracticability of the improvement of Java indigo by chemical selection have been confirmed by an independent examination of the question

(1) For notes on *H. cannabinus*, see *R* April 1918, No. 420; *R*. Feb. 1919, Nos. 146 and 1140. (*Ld*)

(2) See *R* Jan 1922, Nos. 50 and 101. (*Ld*)

by W. R. G. ATKINS (Indigo Botanist 1920). (See *Science Progress*, July 1921).

One interesting observation on the growth of Java indigo was made during the year which is worthy of record. In 1919 indigo was sown in an uncemented lysimeter with free drainage and splendid crops were obtained and no trace of wilt was observed (1). The stumps were left in the soil and two cuts were obtained the following monsoon (1920) after which a change took place in the physical condition of the soil, drainage became impossible and the plants died. In October 1920, the soil was removed from the lysimeter and at once replaced. Java indigo seed was sown the same day and up to the time of writing two fine healthy cuts have been obtained and the stumps are shooting again. This result appears to be directly opposed to the theory of phosphatic depletion, which has been advocated to account for the well-known difficulties in the growth of indigo in the Bihar soils. Here is a case where Java indigo has been grown for leaf for 3 years in succession in a comparatively small volume of Pusa soil without any falling off in vigour.

PHYSIOLOGICAL INVESTIGATIONS. — Attention is at present directed towards the determination of the factors involved in the observed deleterious action of grass on fruit trees. A mass of results on this question has been obtained during the year which will shortly be published. Another subject under examination is the influence on growth of the various factors involved in poor soil aeration.

A result likely to prove of practical value has recently emerged from these investigations. During the rains of 1920 (a year of short rainfall), and in 1921 up to the end of August, it has been possible to preserve the lucerne crop and to carry it on successfully for two seasons by growing it on flat beds 3 ft. wide with irrigation furrows 1 ft. wide between the beds.

This method is now being applied to the growth for seed of crops like sanai (or Sunn hemp *Crotolaria juncea*), safflower and Java indigo and it is considered likely to prove useful in the growth of jute seed in Bengal where similar monsoon difficulties exist.

A number of observations have accumulated also on the physiological aspects of disease resistance and on the conditions of the root system and of the soil which appear to precede infection by insects and fungi.

In 1921-1922, investigations on the lines indicated in the annual reports and in the publications of the Section, will be continued on the following crops — cereals, tobacco, fibre plants, pulses, oil seeds, fodder crops and fruit, and also on soil aeration and root development. M. L. Y.

228 — **The New Service of Agricultural Ecology in Italy.** — *Nuovi Annali del Ministero per l'Agricoltura*, Year I, Part 2, pp 395-398. Rome, December 1921.

By virtue of Law No. 500 of April 7, 1921, a new Service of Agricultural (Ecological) Meteorology was instituted. Its duties consist in the systematic study of the physical environment in which agriculture is

(1) See R. Oct. 1921, No. 1057. (Ed.)

practised with a view to determining by a well-defined method the principles governing the adaptation of crops to the climate of the different physiographical regions. These studies will at first be confined to such meteorological phenomena as have the most easily measurable effects, but later, with the co-operation of the Geological Bureau, the investigations will be extended to the agro-geological and topographical factors, in order to obtain a complete knowledge of the physical conditions under which farm-crops grow.

The new Service is sub-ordinate to the " *Direzione Generale d'Agricoltura* ", Division IV) (Agricultural Instruction and Experiment), and consists of a Central Bureau of Agricultural Ecology and of several Ecological Stations.

**CENTRAL BUREAU.** — In addition to its directing and centralising work and the usual technical and administrative duties, the Central Bureau is also required to :

a) provide instruments tested by the Central Bureau of Meteorology and Geodynamics, in order that the meteorological observations may be perfectly comparable ;

b) control the varieties from the botanical standpoint, so that the biological data may be comparable as far as possible ;

c) make a comparative study of the thermic and hygroscopic properties of the soil in connection with this line of research.

d) collect the information and data supplied by the station ; control and elaborate such information and data.

As the new Institute develops the Central Bureau will gradually assume the functions of a Central Experiment Station of Agricultural Ecology.

With the kind permission of Prof. Romualdo PIROTTA, the Bureau has carried out some experimental researches in the Botanic Gardens of the University of Rome ; similar work is also being carried on at the Practical School of Agriculture of Rome

**STATIONS OF AGRICULTURAL ECOLOGY (I).** — Of these there are three categories :

a) First-class Stations where parallel observations are made on the course of meteorological phenomena in the air and at various depths in the soil, and on the development of the plants and varieties according to the instructions received from the Central Bureau.

b) Second class Stations where meteorological observations in the air, and observations of plant growth are made.

c) Supplementary Stations. Here independent Studies are carried out without the aid of special instruments on the growth of plants and crop yield in connection with weather conditions.

At the present time these Stations are in direct communication with

(1) In order to form a network of these Stations the State Agricultural Institutes (Agricultural Colleges, Agricultural Stations, etc.) are being utilized and special Stations are in course of construction. (Ed.)

the Central Bureau to which all the data are sent. Gradually as the Directors of the First Class Stations acquire the necessary practice and experience for dealing with this branch of work, the stations will be granted a certain amount of autonomy and will themselves become Regional Centres having subordinate to them the Second Class Stations and the Supplementary Stations within their sphere of operations.

*Registration of Observations.* — For this, two kinds of form are used.

1) A form on which are entered parallel observations on plant-growth and meteorological conditions, determined objectively without instruments. On this form are noted the details (beginning and end), connected with the different growth stages ; germination, tillering, heading, etc. In the case of each, the conditions affecting the plant positively or negatively are also entered.

2) Tables drawn up in the usual manner on which are registered the observations made with the help of instruments.

*Utilisation of the Data.* — By working up the data according to the method proposed by the Bureau, an accurate knowledge is acquired of the connection between a plant and its environment. In the first place the plant is analysed in order to determine, in each given case, the genetic factors or groups of factors governing the behaviour or reaction of the organism under different conditions of temperature, hygroscopicity, etc. noting the deficiency or excess. In the second place a careful examination is made of the environment as a function of the development and yield of the plant, in order to determine amid the complex interplay of the environmental factors, the value or the groups of values, exercising a dominant influence upon the yield, and to bring into prominence the characters of susceptibility and resistance to disease that are governed by the various genetic factors.

A sure basis is thus obtained for the direction of the operations undertaken to lessen the discrepancy between the plant and the conditions under which it grows.

Thus in the case of wheat, definite information is obtained on the following points :

1) Which among all the varieties cultivated in or suitable for introduction into a region is the most suitable for any given locality.

2) The best dates for sowing, so that the times when the plant is most susceptible may coincide with the most favourable periods.

3) The best cultural operations and the most suitable time for carrying them out, in order to counteract the negative action of unfavourable meteorological conditions.

4) These data are also used to direct the breeder who is anxious to unite in the same individual, and in definite proportions so as to obtain the maximum yield, the two characters, specific productivity and resistance to the most dangerous and injurious meteorological conditions.

In short a decrease in risk (as regards weather changes) is thus effected and hence an increased yield without useless outlay, which means a real increase in the value of the capital.

Such systematic and continuous work has to be pursued for a long time

before yielding averages of any value. This branch of work is common to all the Stations, but the Central Bureau recognises the importance of combining general research work with the study of local problems and has directed the different Stations to investigate the difficulties that arise in their immediate neighbourhood.

Since 1919, under the auspices of the Società degli Agricoltori italiani (now the Istituto Nazionale d'Agricoltura), the Director of the Service has been engaged in drawing up a biological census of wheat (1) and has sent the following list of questions to the Directors of all the Agricultural Institutes of Italy.

1) What meteorological conditions are injurious to wheat? State in the case of each at what time in the growth period of the plant it occurs, and the number of times in a decade.

2) What are the fungoid diseases and other causes of reduced yield of which the appearance and development are closely connected with the state of the weather?

3) What varieties of wheat are cultivated? State in the case of each:

- a) The area occupied in % of the total area under wheat;
- b) If this area tends to increase or diminish, give the reasons;
- c) How does the wheat behave under unfavourable meteorological conditions.

Useful replies to these questions were given in 194 cases.

The material thus collected will not only furnish data for a monograph on climatic conditions of wheat-growing in Italy (which is soon to be published) but, after the necessary tests have been made and the results verified, will show, in the case of each district, the most important meteorological problem which must be investigated and explained without delay.

The Ecological Station have therefore a twofold object:

- 1) *general* (the systematic study of the environment).
- 2) *special* (the study of local problems).

\* \* \*

The Bureau will publish synthetically all the results obtained, and will send all information and suggestions of a useful and practical character to the following Institutions:

1) Agricultural Experiment Stations' and "Cattedre ambulanti d'Agricoltura" (in the case of all questions connected with the choice of varieties, the optimum date for sowing and for other operations).

(1) By the Decree under date of February 20, 1920, this census is extended to all the wheat-growing countries and the data thus obtained will be used in the preparation of a general monograph on the Climatic conditions of Wheat-Growing. (Ed.)

2) Institutes of Genetics and Phytotechnical Stations. These will receive :

a) An account of the researches undertaken for the purposes of determining accurately the physiological region where a new variety can be introduced with success ;

b) All ecological data that will guide students of heredity in their researches as far as the conditions of the physical environment are concerned).

3) Bureau of Irrigation (information regarding the dates when irrigation is necessary).

4) Bureau of Statistics (scientific explanation of statistical data).

5) Institute of Plant Pathology (the Bureau will furnish the data required for organising the control of those insect and fungoid diseases whose appearance and development are clearly correlated with weather conditions).

## CROPS AND CULTIVATION

229 - **Experimental Researches on the Critical Period of Wheat, as Regards Rainfall in Italy.** — AZZI, G., in *Nuovi Annali del Ministero per l'Agricoltura*, Year 1, No. 2, pp 290-307 Rome, December 1921

AGRICULTURA  
METEOROLOGY

The results of a series of experimental researches on the critical period of wheat as regards the heading stage, and on the behaviour of the 4 varieties employed.

These experiments were carried out during the agricultural year 1920-1921, at the Botanic Garden of the University of Rome.

**MATERIALS AND METHOD.** — Varieties of wheat examined: *Apulia* (Rieti × Spelta), *Cervaro*, *Carlotta Strampelli* (Rieti × Massy), seed supplied by M. STRAMPELLI, and *Spella*, seed supplied by MM. ANDRIEUX-VILMORIN.

The fact that one variety, unlike the others, does not suffer from injuries due to drought may be due to various causes :

1) The heading is early or late which displaces the critical period, so that the drought occurs at a time when the plant is less susceptible to its effects.

2) The roots penetrate deeply, thus allowing the plant to draw water from the supplies that have accumulated in the lower strata of the soil when rain is absent, and the surface is insufficiently damp.

3) The plant's structure is such as to enable it to economise water and thus attain the same results (straw and grain production), with less water consumption. This is true drought resistance, and is the object of this work.

The plants were grown in pots filled with the same kind of soil, and were kept under cover in a movable shed during the critical period.

There were for each variety, 20 pots divided into 4 lots or series : A, B, C, and D.

All the pots without distinction were watered copiously from Dec-

ember 29 to April 12 (1st sub-period), and from the 7th day after heading until maturity (2nd sub-period), and therefore did not suffer from any lack of moisture.

In the interval (2nd sub-period) from April 12th to the 6th day after heading (when it is to be supposed that the effect of moisture would be most noticeable), the series *A*, *B*, *C* and *D* were subjected to different treatments.

Series *A* was watered 3 times on May 5, being given 45 mm. each time, and twice on May 8 receiving 30 mm. each time.

Series *B* was given 30 mm. of water twice on May 5.

Series *C* was given one watering of 15 mm. on May 5.

Series *D* was not watered at all.

Pot experiments have many drawbacks, but in the present case they have the advantage of limiting the study to a great extent, and confining it to the question of real drought resistance, by suppressing the effect of root-penetration and of the date of heading.

RESULTS. — The amount of water placed at the disposal of the plant affects the date of heading in so far that the latter is retarded in proportion as the conditions of the environment become worse.

The following phenological data were obtained :

Varieties

Cervaro . . . . .	May 9	May 10	May 15	May 18
Apulia . . . . .	" 13	" 15	" 17	" 18
Spelta . . . . .	" 18	" 25	" 28	June 1
Carlotta Strampelli . . . . .	" 20	" 20	" 21	May 28
General average . . . . .	May 15	May 17	May 20	May 24

This progressive retardation even if it were also to occur under normal conditions in the case of farm-crops, could not fail to have a deleterious effect, as it would induce late maturity in the plants; ripening took place in fact at the same time in all the series, the order being as follows: Apulia, Cervaro, Spelta, Carlotta Strampelli. From the beginning of maturation, the difference between the watered and unwatered plants manifested itself very clearly. The latter developed badly and remained very low; the ears scarcely emerged from the foliar sheath; heading was incomplete and even entirely absent in some individuals.

In the Apulia variety the tendency to shrivel up, manifested by the leaf-blades was noticeable, some becoming almost spike-like in shape (in the series *C* and *D*), which reduced the respiration surface.

All the plants gathered were biometrically examined with regard to the following characters: length of culm; weight of culm; length of ear; weight of ear; number of grains per ear; weight of grains per ear; weight of each grain; weight of rachis. All these characters are posi-

tively associated with the straw length, and should vary according to the same rules.

The author has limited himself to giving the data that are absolutely necessary for the purpose of demonstration. In the Tables the numbers marked with an asterisk represent values lower than those calculated, probably due to the difficulties experienced in maintaining absolute uniformity of conditions in all the pots.

In estimating the data and the harvest, the twofold object of the work must never be lost sight of:

1) The experimental proof of the existence of a critical period for wheat as regards rainfall at the heading stage;

2) The special behaviour of the 4 varieties examined.

As regards the grain yield, its direct relation with the rainfall during the critical period was clearly shown, increasing the watering also increased the weight of the grain borne by each ear. On taking the average of *A*, *B*, and *C* and comparing it with *D* the difference between the watered and unwatered plants is still more striking (See Table I).

The 4 varieties may be divided into a 2 lots according to their special behaviour. Cervaro and Apulia *most drought-resistant*, and Spelta and Carlotta *least drought resistant*.

1) *Spelta and Carlotta*. -- The yield of the unwatered pots was very scanty; if the amount of water is increased, the yield also increases rapidly and the difference between the two lots, the unwatered and the watered, which can be expressed by the quotient obtained by dividing the average of *A*, *B*, *C* by *D*, is very high: Spelta = 2.6; Carlotta = 3.0.

2) *Cervaro and Apulia*. -- The return, even from the unwatered pots, is relatively high — 3 to 4 times more than in the case of Carlotta and Spelta. With the progressive increase of the amount of water placed at the disposal of the plant, the increase in the weight of the grain is less rapid than in the preceding case, and the difference between the average of *A*, *B*, *C* and that of *D* is somewhat slight. In fact, the quotient is reduced to 1.1 and 1.2 for Cervaro and Apulia respectively. Similar conditions are found again as regards the weight of each seed; this can be also considered as an index of the quality of the product (see Table III). In Carlotta Strampelli, there is a regular, ascending curve from *D* to *A*. Thus,  $D = 1.5$  cg;  $C = 1.9$  cg;  $B = 2.6$  cg,  $A = 3.0$  cg.

The straw yield, both from the standpoint of the weight and the length of the culms, confirms as regards the existence of the critical period, what has already been observed in the case of the grain: the weight and length of the culms increases with the increase in the amount of water given (See Table III). Cervaro gives the most regular curve:  $D = 53$  cm;  $C = 61$  cm.;  $B = 74$  cm.;  $A = 77$  cm.

In series *D*, the difference between the Cervaro-Apulia group and the Spelta-Carlotta group is very great (Cervaro = 53 cm.; Apulia = 53 cm.; Spelta = 36 cm.; Carlotta 35 cm.) and it remains the same, unlike what has been found in the case of the grain; this also applies to the 4 varieties (from 1.4 to 1.5).

The correlation between the length of the ear and the amount of water given during the critical period, is on the contrary a little less close, in spite of the positive connection between the length of the culms and the length of the ear. The correlation coefficient for Apulia is almost reduced to zero: in the series *D*, the length of the ears is almost the same as in series *A*, and is greater than in *B* and *C*. This capacity of reducing the growth of the culm, under unfavourable conditions without shortening the ear, might be interpreted, given further verification, as a character of adaptation to drought.

As regards the characters: weight of ear, number of grains per ear, etc. which are positively correlative with straw length, the same general observations hold good as those made in the case of straw length.

GENERAL CONCLUSIONS. — 1) The existence of a critical period (occurring in the interval between the 6th day before heading and the 6th day after the appearance of the ear), is entirely confirmed by these experiments. The straw length and all the correlative characters are increased (rise in value) with the increase in the amount of water placed at the disposal of the plant during the critical period.

2) The four varieties of wheat examined can be divided into two groups according to their behaviour as regards the above-mentioned phenomena:

A) Apulia and Cervaro, more resistant to drought.

B) Spelta and Carlotta, less resistant to drought in the following order: Cervaro, Apulia, Spelta, Carlotta. This order may however, be somewhat modified by the further experiments in progress: the growth of the plant and its grain yield also depend upon the specific productivity of each variety, which has not yet been accurately determined.

3) The actual productivity of a plant is the result of a compensation established between specific productivity "and resistance to the most injurious environmental factor."

The productive capacity usually decreases with the increase in vigour; hence, a plant that is very resistant to drought and unfavourable meteorological conditions, even if provided with the best environment for its development, always gives a relatively low yield.

On the other hand, a vigorously growing variety bearing large ears (high specific productivity), but not possessed of the necessary drought-resistance, when placed in dry surroundings does not develop at all, or only produces seed that cannot set. Of this Carlotta Strampelli is the typical case; this wheat is also endowed by heterosis with a high specific productivity that manifests itself with the progressive improvement in the environmental conditions. On the present occasion, the plant did not succeed even when watered 5 times, in completely filling the grains which still remained shrivelled.

Spelta is certainly possessed of a much lower productive capacity.

As for Cervaro and Apulia, there are not enough data to be able exactly to estimate their xerophily: even from observations made during its vegetative period, Apulia seems to have very distinct capacity for adapt-

ing itself to a dry climate; the greater productivity of Cervaro might therefore be attributed to a greater specific productivity which is however always below that of Carlotta, and ran no risk of being impaired by the lack of moisture to which it was subjected in the course of the experiment.

In Cervaro it would appear that specific productivity and drought resistance are united in the best proportions.

TABLE I. — *Weight of Seeds per Ear in cg.*

Varieties	Number of waterings					Difference between watered (a) and unwatered plants (s)	$\frac{a}{s}$

230 — **Evaporation and Other Soil Properties found to be Connected with Soil Constitution.** — I KEEN, B. A (Goldsmiths' Company's Soil Physicist, Rothamsted Experimental Station), The Evaporation of Soil. Influence of Soil Type and Manurial Treatment, in *The Journal of Agricultural Science*, Vol. XI, Part 1, p 132-140, figs 2 Cambridge, October 1921. — II. KEEN, B. A., and RACZKOWSKI, The Relation between the Clay Content and certain Physical Properties of a Soil, *Ibidem*, pp. 441-449, Figs. 5.

SOIL PHYSICS

In an earlier paper (1) the author had shown that the essential difference in the evaporation from sand and soil was primarily due to the colloidal portion of the clay fraction in the soil, and secondly, to the organic matter present. The experiments now described were carried out on two soils,

(1) See R. 1015, No 248. (Ed)

one of which contained about 6 % of clay, and the other 15 %. In order that the influence of manurial treatments could be studied at the same time, samples were taken of each soil from the unmanured plots, and plots given farmyard manure, and complete artificial manure, respectively. The rate at which the soils lost water over concentrated sulphuric acid and at a constant temperature, was found to depend firstly, on the amount of clay present, and secondly on the amount of organic material in the soil. The differences due to content of organic material were more obvious in the soil containing the larger amount of clay, the farmyard manure plot lost water at the slowest rate and the unmanured plot occupied an intermediate position.

In the sandy soil, the differences in evaporation due to manuring were small.

There is evidence that the moisture equivalent of these soils, measures the percentage of water at which the evaporation is first directly affected by the soil particles and that, at percentages of water in excess of the moisture equivalent, evaporation is taking place substantially from a free water surface.

II. — It is well known, that the behaviour of most soils, is largely determined by the percentage of clay they contain, for this reason the authors proposed to measure various fundamental properties of a given soil (such as pore-space, apparent and real specific gravity, volume, expansion of soil when saturated) at different depths and as affected by the clay content.

The results obtained showed that the weight of unit volume of air-dry soil, viz., its apparent specific gravity, and its real specific gravity, varied inversely with the percentage of clay in the soil, whereas the amount of water it takes up, pore space and volume expansion when saturated, varied directly with the clay percentage. The effect on the constants of the larger quantities of organic matter present in the top two layers of soil of 15 cm. and from 15 to 30 cm. was, weight for weight, approximately equal to that of the clay, except in the volume expansion results where the effect, if any, was within experimental error. It is possible that a fine silt fraction with an upper limit of diameter of 0.005 mm. may have similar effects to the clay fraction.

**231 — The Chlorine Index as a Comparative Measure of the Nitrogen Content of Soils.**—

VEIL C, in *Comptes rendus de l'Académie des Sciences*, Vol. CLXXIV, pp 317-319, Paris, January 30, 1922.

Hypochlorite of sodium when in contact with arable soils, loses its active chlorine. It has been shown that the amount of chlorine which thus disappears is connected with the humus content and affords an index of the probable fertility of the soil (1).

The author adopted the same method in order to discover whether any correlation exists between the chlorine index thus determined and the nitrogen content. He investigated the connection between the amount

(1) *See R.* 1919, No 424. (*Ed*)

of chlorine in the soil ( $\text{cm}^3$  per  $\text{cm}^3$ ), and the nitrogen present (gm. per 100 dry weight), using for the purpose soils for which, as far as is known, no chemical fertilisers had been used. A certain number of samples came from the neighbourhood of Paris, others from Brittany, Haute-Marne and Morocco, there were 20 in all.

Generally speaking, the higher the chlorine index the greater the nitrogen content of a soil. Three classes can be clearly distinguished:

1) Very rich soils, where the nitrogen content is above 4 per 1000 and the chlorine index higher than 30.

2) Soils with a low humus content, where the nitrogen content is above 1 per 1000 and the chlorine index varies between 7 and 12.

3) A series of soils of average richness, with a nitrogen content varying between 15 and 27, and chlorine indices above 1 per 1000 and below 2 per 1000

232 -- **Researches on the Presence of Arsenic and Iodine in Soils and Subterranean Water in Argentina.** - I. RICHART, F. TRELLIS. R. A. (Laboratorio Químico de Investigaciones Agropecuarias, Facultad de Agronomía y Veterinaria, Universidad Nacional de Buenos Aires), Sobre la presencia del arsénico como elemento normal en las tierras vegetales, in *Revista de la Facultad de Agronomía*, Vol. III, Part 3, pp. 281-284, 1 pl., bibliography of 9 works, Buenos Aires, December 1927. - II. IDEM, Iodo y arsénico en las aguas subterráneas, *Ibidem*, pp. 285-287, 1 fig., bibliography of 12 works.

The classical researches of GAUTIER have proved that arsenic is normally present in the animal organism. JADIN and ASTRUC have shown that this arsenic comes from vegetable foods, and as the plants consumed must obtain their supply of this substance from the soil, it is necessary to determine the arsenic content of the latter.

For this purpose the authors analysed the Argentina plant products. Arsenic was always found in the latter, but in smaller quantities than had been observed in Europe, except in the case of the seeds for instance of wheat grain harvested in regions where the soils are rich in arsenic. The authors analysed 20 different soil samples and found the arsenic content varied from 0.08 mg. to 2.25 mg. for 100 gm. of air-dried soil; it was not possible to determine the relation between the amount of arsenic and iron present, but it was found that arable soils always contained arsenic and that there was no connection between their chemical composition and their arsenic content. The latter is highest in the upper layers and decreases with the depth.

Although there is no general rule, it appears possible that some connection may exist between the amount of arsenic in the soils and in the subterranean waters beneath them, as has been observed in an arsenical district (North Santa Fé).

It should be remembered that iodine and arsenic are constantly present in the waters of the pampas, their amount depending on the chemical composition of these waters, and on the geological nature of the soil. Water containing chlorine, sulphur and sodium bicarbonate have the highest iodine and arsenic content, while those coming from granitic or calcareous soils have the lowest. The iodine may be derived from marine deposits.

but it must not be forgotten, that it is of constant occurrence in soils, atmospheric dust and freshwater algae, and also that all other plants are relatively rich in iodine, as has been shown by the researches of GAUTIER and others.

233 - **Concentration of the Hydrogen Ion in the Soil and in Plants.** — I. ATKINS, W. R. G., Some Factors affecting the Hydrogen Ion Concentration of the Soil and its Relation to Plant Distribution, in *The Scientific Proceedings of the Royal Dublin Society*, Vol. XVI, n. 5, Nos. 30-34, pp. 369-423. Dublin, 1922. — II. IDEM, The Hydrogen Ion Concentration of Plant Cells. *Ibidem*, p. 414-426. — III. IDEM, Note on the Occurrence of the Finger and Toe Disease of Turnips in Relation to the Hydrogen Ion Concentration of the Soil, *Ibidem*, pp. 427-434. Bibliography.

I. — The author gives a critical review of the literature dealing with the concentration of the hydrogen ion in the soil, and the factors exerting an influence upon this concentration and its relation to plant distribution. He reaches the following general conclusions.

In the first place it is desirable, in order to determine the fundamental relations existing between the ions present in the soil solution and its hydrogen ion content, to consider separately the effects of the different salts. When water is in contact with pure calcium carbonate the theoretical maximum alkalinity is only pH 9.01 (1) which may be attained experimentally in the absence of carbon dioxide. The corresponding bi-carbonate in equilibrium with the gases of the atmosphere is pH 8.37 at 16° C becoming more alkaline at higher temperatures. Owing to the high content of carbon dioxide in the soil, the pH values of limestone soil are usually lower and they vary with the aeration.

The theoretical maximum alkalinity for magnesium carbonate is pH 10. Dolomite soils may thus attain to greater alkalinity than limestone soils. Alkalinity of over pH 10, due to sodium carbonate, may be reduced to pH 8 by the addition of calcium sulphate. The former reaction is injurious or destructive to plant cells, whilst the latter is favourable to most plants.

Soil acidity may be occasioned by the oxidation of sulphur from iron pyrites. This acidity favours the production of available phosphate and is accordingly beneficial to certain plants. Owing to production of carbonic acid by bacteria, a soil extract may decrease in alkalinity from pH 8.7 to 7.2 or less; the result in the soil appears to be to render iron salts more readily available in calcareous soil when inundated, than when uncovered. The alteration is usually more rapid in soils from the top 6 inches than at greater depths.

Continuous manuring with sulphate of ammonium or of potassium, decreases the effective soil alkalinity, even in a calcareous silt, but by a small amount only, about pH 0.2-0.4 in the cases examined.

An acid soil extract is only slightly altered by boiling; in one instance, from pH 5.4 to 5.7. Alkaline extracts tend to reach the maximum value for calcium carbonate pH 9.0. Higher values, such as pH 9.2, appear to indi-

(1) See R. February 1919, No. 159 (*Ed*)

cate the presence of magnesium in small amounts. The altered reaction is probably of importance in inhibiting the growth of certain soil organisms in heated soil.

When arranged in order of decreasing alkalinity, soils derived from different materials stand as follows: — calcareous silt, limestone, sandstone, calcareous tuff (schalstein) with slate, ordinary state, pillow-lava (spilite), felsite and granite. The values are modified in certain places, for proximity to the coast lessens acidity and a high gradient often increases it. The results relate mainly to Devonian strata and the accompanying volcanic or plutonic rocks.

The author gives figures for the hydrogen ion concentration of the habitats of over a hundred native plants. These show that the measurement is a valuable index of various soils conditions and that many plants are limited to a short range of pH values; others with a wider range occur within certain definite pH values, but some plants grow well at widely different soil reactions. A distinction must be made between acid peaty soils, acid clay soils and acid sandy soils. It is interesting to note that wild flowers grown in a garden, do best when the soil reaction is similar to that in their native habitat.

Natural waters, even from the peaty districts examined, contain no acid other than carbonic. Water in a spring may be at pH 6.4 and the stream flowing from it at pH 8.3 when in equilibrium with the atmospheric concentration of carbon dioxide. Photosynthesis may raise water containing magnesium salts to pH 9.7. The hydrogen ion concentration of natural soft waters, tends to increase during winter and to decrease in summer.

II. The author then treats of the hydrogen ion concentration within the plant and in the actual living cells, and gives a brief account of the previous work on the subject from which he draws the following conclusions.

Plant cells are rarely alkaline and pH 8 is not exceeded in them. On the acid side pH 1.4 has been observed. By a microchemical method it is possible to determine the pH values of the cells and tissues; it has been found that the xylem is more acid than the pith and medullary rays, and the midrib of a leaf is more acid than the parenchyma. Parenchymatous tissue is often in the neighbourhood of pH 6, while woody tissue is nearer pH 5, or more acid. When grown in alkaline or neutral soil, the root is usually less acid than the other parts of the plant. The author reserves the influence of soil reaction for consideration in another paper.

It has been pointed out that the pH value met with in a tissue is usually near but slightly less than the optimum for the activity of the characteristic enzyme at ordinary air temperature. This ensures that the acidity does not destroy the enzyme at such higher temperatures as may be experienced by the plant under natural conditions.

III. — It has long been known from the results obtained by VOELCKER and other workers (which were collated by HALL in 1910), that finger-and-toe disease occurs in soils poor in calcium salts. The author mentions the case of two adjacent turnip fields of similar clay soil one of which was

badly infested with finger-and-toe disease in the crop, while the other was entirely immune. It was found that the calcium content (calculated as oxide), was respectively 0.17 % and 0.40 %; the hydrogen-ion concentration of the samples was respectively pH. 6.6 and pH 6.7. In other words, the soil of the infected field was the more acid and it would be useful to determine the pH limits within which the fungus producing finger-and-toe disease (*Plasmodiophora brassica*), is able to develop. G. A. B.

234 - **Researches Made in Denmark, upon the Effect of Soil Conditions on Bacterial Life and the Chemical Transportations taking place in the Soil: the Capacity for Decomposing Mannite.** — CHRISTENSEN H. R. (145 Beretning fra Statens Forsøgsvirksomhed i Plantekultur), in *Tidsskrift for Plantekul.*, Vol. XXVIII, Part 1, pp. 1-58, figs. 5 Copenhagen, 1922

The author has previously had occasion to study the power of fixing atmospheric nitrogen, possessed by different soils. The soils were mixed for this purpose with mannite and put for some weeks into a thermostat to incubate (1). The observations made seemed to show that there are considerable differences in the mannite decomposing-power of various soils, and as it also appeared probable that these differences were connected with the agricultural properties of the soils, it was thought well to investigate the whole question of how far a capacity for decomposing mannite depended upon the nature of the soil. A satisfactory method of research was first selected, whence it was found that the moisture content of a soil determines the rapidity as well as the course of the mannite decomposition process, and that in order to attain the approximate maximum decomposition, the humidity must be about 75 % of the water capacity of the soil. Since a large number of ordinary soils had been used the author tried to discover the capacity of mannite decomposition as shown by the rapidity of this process, and following his predecessors, he investigated both inoculated and uninoculated cultures in order to determine the differences due both to the chemical composition and microbiological nature of the soil. He also determined the reaction of the soil samples, and the phosphoric acid soluble in hydrochloric acid and carbonated water respectively, and finally the amount of lime and magnesia soluble in 10 % ammonium chloride.

The author first found that the rate of the mannite decomposition varied within very wide limits; in certain cases, the process was completed in 5 days, in others it was not complete even at the end of 30 days. After due consideration it would appear that there is a definite relation between the reaction of the soil (especially within limits very close to the point where it becomes neutral) and its power of decomposing mannite, for soils that are shown to be well-supplied with lime, and are thus favourable to the development of *Azotobacter*, generally have a greater capacity for decomposing mannite than those having a deficiency of lime and lacking *Azotobacter*. This difference is still more noticeable, if distinctly acid or alkaline soils are compared. There are however notable exceptions to this rule, these seem on the one hand to show that soils with sufficient

(1) See R. 1917, No. 996. (Ed.)

lime possess, more often than those deficient in it, the qualities determining the rapidity of the mannite decomposition process, while on the other hand, no connection has been found between the amount of phosphoric acid soluble in hydrochloric acid present in a soil, and its capacity for decomposing mannite. On the other hand, soils needing no lime, and with much phosphoric acid soluble in water containing carbon dioxide, have also a great power of decomposing mannite; in fact if the concentration amounts to 1.2 mg. of phosphoric acid per litre, mannite decomposes very rapidly in such inoculated soils, with but rare exceptions. Further, the decomposition of mannite takes place as a rule much more quickly in inoculated, than in uninoculated soils; usually however the differences are slight, so that we are justified in saying that the degree in which mannite is decomposed depends chiefly upon the chemical composition of the soil.

In order the better to understand the effects of the chemical factors, the author treated the soils with lime and various phosphate salts. The results proved that the rapidity of the mannite decomposition depended upon the presence of slightly basic lime compounds and readily soluble phosphoric acid.

These facts are of great importance, but further research is necessary with regard to the extent to which the speed of the mannite decomposition in soils needing no lime, may be an index of the amount of phosphate compounds present that are very soluble and capable of speedy assimilation by plants; such an index being afforded by the *Azotobacter* test in the case of soils that are deficient in lime.

A first step taken in this direction by the study of a series of soils proved, by a series of field experiments lasting for several years, to be lacking in phosphoric acid. The results were very satisfactory, for they showed that these soils, which agricultural experience had proved to be decidedly in want of phosphoric acid, had a very low capacity for decomposing mannite, whereas soils well provided with phosphoric acid broke up mannite quickly. Further, when normal amounts of superphosphates are applied for a certain number of years to soils requiring phosphoric acid, the mannite decomposing capacity of these soils is greatly increased. The experiments so far made are, however, not sufficiently extensive to warrant any conclusions as to the practical value of this method in determining the phosphoric acid requirements of the soil.

In the latter part of the article, the author deals with the connection between the reaction and basic character of the soil, and its content in phosphoric acid soluble in hydrochloric acid and in water containing carbon dioxide, and of lime and magnesia soluble in ammonium chloride. These correlations show very clearly that an alkaline reaction and the presence in the soil of certain basic compounds, like those of lime, are necessary conditions of a somewhat high content of phosphoric acid soluble in water containing carbon dioxide, and finally, that the form under which phosphoric acid is found in soils is determined to a large extent by their reaction

METHODS  
OF  
CULTIVATION

235 - The Spring Awakening of Arable Land and the Choice of Agricultural Machines. — RINGELMANN, M., in *Journal d'Agriculture pratique*, Vol. 35, No. 7, pp. 132-135 Paris, February 19, 1921

The author considers LUMIÈRE's paper (1) on the "Spring Awakening of Arable Land" from the point of view of the agricultural machines and operations required. All that is needed is some simple apparatus mounted on a stubble-plough, a pulveriser, or a cultivator with flexible teeth.

According to LUMIÈRE, the roots of plants and also the dead leaves and aerial portions of annual plants secrete toxic products that are inhibitory agents preventing the seeds germinating, and should therefore be removed as quickly as possible by fermentation, oxidation or dilution.

This hypothesis explains the beneficial effects of various cultural operations: dry-farming, ploughing fallow land for a year, the repeated use of a cultivation with flexible teeth instead of ploughing (JEAN method) (2), etc.

It also shows that it is necessary in preparing the autumn seed-bed, only to loosen the soil to a slight depth without turning it but at the same time to dig and subsoil it as deeply as possible, in order to facilitate the free passage of the rain, which first washes the superficial layers of the soil, promoting the germination of the seeds they contain and then, passing on to the greater depths, removes the toxic products from the lower strata at the time the roots of the new plants will reach them. The toxic products would thus be present in relatively large amounts in the lower layers of soil.

The furrows then act as small elementary drains that hasten the removal of soluble substances by the rain water. For this reason it is advisable to use implements with coulters that are relatively narrow for most of their length, but wider at the point, so as to make narrow channels; the section of the latter should be smallest when the soil is most compact and heavy, as this minimises the compression and slipping of the earth.

Ploughing should therefore not be carried to a depth exceeding 10 to 15 cm. After the harvest has been carried, it may be assumed that the toxic products are most abundant in stratum *l* (fig. 1); after ploughing, this stratum, which is for the time unsuited to germination, is arranged in parallel inclined planes *l'*; these after the passage of the roller or harrow take up the position *l''*, so that the seeds finding themselves from the beginning under good germinating conditions are those occupying the triangles *g*; those situated elsewhere will germinate later when the rain has washed the superficial layers. Instead of ploughing to the depth *yo*, it would therefore be better not to go deeper than *yn*, the exact figure is to be found by experiment. It is however, also advisable to loosen the soil *in situ* to the depth *nm*, in order to allow the rainwater to drain away easily and free the strata *nm* from toxic products, before the roots of the crop have penetrated so far.

The best agricultural machines to use are stubble ploughs working to a depth of 7-10 cm., or pulverisers penetrating to 5-8 cm., provided each

1) See *R.* Jan 1921, No. 11, (14)

2) See *R.* April 1916, No. 386 (14)

mould-board *A* (fig. 2) is fitted with digging claws or teeth *f* which penetrate as deeply as possible, 20-25 cm. for instance, before the furrow is cut by the plough.

Fig. 1. — Transverse section of ploughing.

Fig. 2 — Principle of stubble-plough with digging teeth.

Fig. 3. — Principle of cultivator digging coulters.

Such digging teeth, which resemble coulters, may be introduced between the disks of the pulveriser.

The same principle can also be applied to cultivators. In this case, it would be necessary to affix the digging coulters shown diagrammatically

at *c* (fig. 3), behind each share (*s*) of the cultivator (or every second share), the latter working a breadth of 12.5 cm. (teeth per metre of width of the carriage), and to a slight depth. The distance between the verticals *y* and *y'* by passing the extremities of *s* and *c*, which will give most work with the minimum traction, must be determined by experiment.

After the passage of the above-mentioned machines it is well to use a clod-breaking roller to consolidate the surface. The roller, which must be of the required breadth, can be attached to the back of the machine. The loosened superficial layers must settle down, for in LUMIÈRE'S experiments its consolidation is proved by the water used for washing the soil.

The seed being sown at depths varying from 3 to 6 or 7 mm., it is only necessary to loosen the soil to a depth of 10 cm. in order that the first rains can rapidly wash the surface.

What has been said refers solely to the preparation for the autumn sowing, for in the spring the rains and snows of winter insure the soil being washed to a depth below where the seeds are lying. Further, the ground is well ploughed in the autumn, and superficially ploughed several times in spring, which agrees well with LUMIÈRE'S experiments.

G. B.

**MANURES  
AND  
MANURING**

236 - **The Conversion of Straw into Farmyard Manure.** - HUTCHINSON, H. B. and RICHARDS, E. H., in *The Journal of the Ministry of Agriculture*, Vol. XXVIII, No. 3, pp. 398-411, figs. 2, London, August 1921.

As a result of the recent extension of the area under cereal crops, it was thought that there might remain a surplus of straw which could not be employed for the usual purposes of stockfeeding and litter. It was therefore determined to investigate the possibility of converting it directly into manure, in order to supply the market-gardeners who found it increasingly difficult to obtain adequate supplies of stable-manure.

As a result of experiments carried out at the Rothamsted Experimental Station, a method was devised by which straw can be converted into a substance having many of the properties of stable manure.

In a considerable number of the preliminary experiments, to secure the usual disintegration and colour changes in fermenting straw, the most promising results were obtained when the straw was subjected to the action of a culture of aerobic, cellulose-decomposing organisms (e. g. *Spirochaeta cytophaga*). Further enquiry showed, however, that this effect was not due simply to the presence of an organism capable of breaking down cellulose, but rather to the indirect effect of the mineral substances contained in the culture fluid. From this stage onwards, the question of food supply, as distinct from the addition of any particular species of organism, received special attention and the results obtained were of both theoretical and practical importance.

The great importance of air supply, was shown by an experiment in which 4 lots of straw were fermented under aerobic and anaerobic conditions for 3 months at 37° C. The results were as follows:

	Loss of dry matter	
	Straw without Nitrogen	Straw with Nitrogen
Without air supply . . . . .	16.3 %	17.1 %
With air supply . . . . .	40.1	58.9

As a rule special measures to maintain a favourable temperature are not necessary. Moist straw rapidly undergoes a preliminary fermentation during which the temperature may rise to over 65° C. It is, however, in the subsequent stages that the effect of treatment has most effect in maintaining the temperature. Experience has shown that a supply of nitrogen, by increasing the energy of fermentation, leads to an increase of 15-20° C in favour of straw which has received a sufficient supply of nitrogen, as compared with untreated straw.

Repeated experiments have proved that the most rapid break-down of straw occurs when some source of nitrogen in an available or indirectly available form was supplied, but only when the reaction of the solution was neutral or slightly alkaline. The addition of urine, urea, ammonium carbonate or peptone, with certain concentrations, immediately sets in train rapid decomposition changes. The highest concentration for quick break-down is appreciably below that of the weakest undiluted urine; hence it is quite impossible to obtain well-rotted dung by the use of neat urine without considerable loss.

Equally good rotting may be obtained without loss of nitrogen, as was shown by experiments in which straw was incubated with urine in different concentrations for periods up to 86 days; even after this period, the losses that occurred with satisfactory rotting and within the lower concentrations, were only about 4 % of the final nitrogen. The ordinary losses of the manure heap are frequently more than tenfold this amount.

In addition to the two phases already mentioned *a*) in which the straw supersaturated with nitrogen loses it to a definite degree, and *b*) in which straw with the requisite amount of nitrogen may undergo rotting without appreciable loss and is therefore in a state of equilibrium, there is a third phase, in which undersaturated straw exhibits a well-marked property of fixing nitrogen by the agency of micro-organisms, especially in the form of ammonia, until the same final content of nitrogen in the rotted product is attained.

As a rule, the nitrogen retained by supersaturated straw (that is to say straw containing more nitrogen than will remain in the final product), and such as is accumulated by undersaturated straw (*viz.* straw containing less nitrogen than the amount present in the final product), appears to be stored up in an organic, or non-ammoniacal form. The maximum retention of nitrogen has been found to occur within the first 4 weeks, after which the breakdown of this organic nitrogen to ammonia and the

consequent loss by volatilisation seems to keep pace with the loss of dry matter. Finally the material assumes a "stabilised" condition, the loss of nitrogen becoming greatly diminished or even absent altogether for long periods.

Between the 60th and the 120th day little change is found to take place, either in the amount of stable or fixed nitrogen, or in the proportion of this nitrogen and the ammonia which appears to be held by fermented material even at a high temperature (37°C), in spite of constant handling. In general it may be stated that when straw has worked from an unsaturated to a stable phase, little or no free ammonia is to be found, but straw which starts with a superabundance of nitrogen, appears to hold, when in a fermented state, upwards of 14 % of its nitrogen in the form of ammonia so long as the material is in a moist condition. Desiccation leads to almost complete loss of ammonia and in this respect, as well as in the proportion of ammonia in the moist material, the artificial manure resembles natural manure.

From the study of the inter-relations between nitrogen and straw the authors have come to the conclusion that the amount of nitrogen necessary for pronounced rotting, and the amount the straw is capable of "fixing" in the form of ammonia are identical, and that in general, the figure varies only between 0.70 and 0.75 parts of nitrogen per 100 parts of dry straw. Within these limits fermentation proceeds without loss of nitrogen, and it is obvious that except in so far as the nitrogen content of the original straw varies, the final "stabilised" product obtained when rotting has proceeded to an appreciable extent must likewise exhibit comparatively slight variation in its nitrogen content. If for example the nitrogen content of the original straw was 0.5 %, and we assume that the theoretical amount of ammonia nitrogen equal to 0.72 lb of nitrogen per 100 lb. of straw, has been fixed, then with a loss of 40 % of dry matter during fermentation, the resulting rotted straw will contain

$$(0.50 + 0.70) \times \frac{100}{60} = 2.03 \% \text{ of organic nitrogen in the dry matter}$$

The data thus obtained lead to a consideration of the process of inducing the fermentation of straw on a large scale, and can also be applied to the conditions operating in the production of ordinary farmyard manure.

As regards the preparation of artificial manure (1), experience has shown that urea and ammonium carbonate are the most suitable carriers of nitrogen, since they insure favourable alkaline reaction, and the rapid decomposition of the straw, but as they are very expensive, it is best in large scale experiments, to use cyanamide or sulphate of ammonia. While cyanamide already contains sufficient free lime to keep in check any acid compounds formed during fermentation, sulphate of ammonia must be supplemented by the addition of a base, and for this purpose finely ground chalk, ground limestone or waste lime from causticising plant at soap-

(1) This process, as well as its application to the purification of sewage has been covered by Letters Patent, (Brit Patent No 152387) (Author's Note)

works may be used. For general purposes, it will be found that upwards of  $\frac{3}{4}$  cwt. of sulphate of ammonia and 1 cwt. of finely ground carbonate of lime per ton of straw are sufficient to induce fermentation. The main obstacle to large scale operations arises from the great tardiness with which raw straw takes up the moisture necessary for fermentation. Where pits are available, this difficulty may be overcome by allowing the straw to remain immersed for 2 to 4 days, after which the free liquid may be drained off. In the case of heaps or stacks on open ground, no advantage appears to be gained by continued wetting with large quantities of water and the authors suggest sprinkling the heaps comparatively lightly with water and allowing a couple of days to elapse before repeating the operation. The slight fermentation that sets in after the first sprinkling renders the straw more capable of absorbing the water of the second. When examination has shown that the interior of the heap has become uniformly moist, the source of nitrogen may be applied in the form of solution; or in the case of cyanamide and other products, this may be broadcasted over the surface of the heap and watered in.

Artificial manure is identical in physical properties with well-rotted farmyard manure, and differs from it in chemical composition only in so far as it does not contain (in addition to nitrogen), the appreciable quantities of phosphorus and potash derived from the foods consumed by the animals. Of the three constituents ordinarily present in manure - urine, faeces and straw - the faeces appear to contribute only to the physical character of the product; and as the nitrogen they contain is inert require to be furnished with the nitrogen needed for the decomposition of the straw instead of fixing it themselves. The average of 26 analyses of the faeces of the horse, cow and sheep showed the percentage of nitrogen to be almost the same as in fermented straw, viz. 1.93. The mean content of fixed, that is to say not ammoniacal, nitrogen in manure made under controlled conditions in America and Europe proves to be 2.09 %, as a mean of 43 records. During the rotting of dung, a large amount (over 40 or 50 %) of the nitrogen contained in the food and litter is almost invariably lost, and this loss appears to fall largely or even exclusively on the urine nitrogen which is the most valuable constituent of the manure since it is the most readily available. Both chemical and physical measures have been suggested to prevent or reduce this loss, but they have either proved ineffective, or have interfered seriously with the rotting process.

If dung making be regarded as essentially a straw-rotting process, this loss is capable of explanation. It has been seen that the nitrogen-fixing power of straw is strictly limited and that any surplus nitrogen in the form of ammonia is liable to loss by evaporation. It may therefore be assumed that the practice of supplying concentrated feeding stuffs to farm livestock merely results in an increased production of soluble nitrogen, which owing to the normally overloaded conditions of the litter, is liable to relatively greater loss than where such feeding stuffs are not used.

A fairly close approximation to the actual results of a number of feed-

ing experiments may be obtained by taking the sum of: 1) the amount of nitrogen present in the litter (which is not subject to loss); 2) the amount of faecal nitrogen calculated by means of the digestion coefficients of the food consumed; 3) the nitrogen that the litter is theoretically capable of fixing (0.72 lb. per 100 lb. of straw); 4) the ammoniacal nitrogen present in the manure.

For this reason the authors advise a more liberal use of litter as a means of reducing the losses that occur in the making of manure.

F. D.

237 - **Supplies of Organic Matter in the Soil; Research carried out at the Rothamsted Experimental Station (England).** — RUSSELL, E. J. (Director, Rothamsted Experimental Station), in *The Journal of the Ministry of Agriculture*, Vol. XXVIII, No. 6, pp. 779-782, figs. 2, London, December 1921

Recent experiments emphasise the importance of having ample supplies of organic matter in the soil, although some of the older agricultural chemists were inclined to the view that artificial fertilisers were the chief source of soil fertility and all that need be done was to apply them in the required amounts. Organic matter however as supplied by farmyard manure improves the conditions for the root-crops, facilitating the production of tilth and increasing the water-holding capacity of the soil. It also improves the growth of clover, and causes less variation in yield from year to year than artificial manure; further, its use involves less risk of deterioration of soil when the course of cropping is abnormal, as in cases where the field receives an insufficient amount of fertiliser, or a manurial treatment deficient in one or more essential constituents.

*Comparison of Farmyard with Artificial Manures.  
Continuous Wheat.*

Plot No	Treatment	Average yield bush. per acre	Mean annual diminution bush per acre	Percentage of relative variance ascribable to weather
2 b	Farmyard manure, 14 tons annually .	34.549	0.031	2.78
3 and 4	No manure . . . . .	12.629	0.097	6.20
5	Complete mineral manure . . . . .	14.180	0.090	5.84
6	As 5 + single ammoniacal salts . . .	22.581	0.141	6.01
7	As 5 + double ammoniacal salts . . .	31.367	0.144	5.11
8	As 5 + treble ammoniacal salts . . .	35.694	0.092	4.18

11	As 10 + Superphosphate . . . . .	22.046	0.219	10.32
12	As 10 + Super + Sulph. Soda . . . .	28.319	0.181	7.28
13	As 10 + Super + Sulph. Potash . . .	30.209	0.123	5.55
14	As 10 + Super + Sulph. Magnesia . .	27.765	0.231	6.38
Alternate } 17	Mineral alone, or double ammoniacal	14.510	0.092	10.16
18	salts alone, in alternate years . . .	29.006	0.114	4.55

The following data, which represent the results of a series of experiments lasting 68 years, prove without any doubt that farmyard manure is more dependable than other fertilisers, although it is not capable of giving as good yields in favourable seasons as a properly balanced mixture of artificials.

The superiority of farmyard manure to artificials is shown by two diagrams. One proves the steadiness of its effects as compared with the effects of a complete manure, phosphatic manure, and a nitrogen-potassic and phosphato-potassic manure respectively, in increasing the yield of continuous crops of barley grown from 1852-1919. The other shows the effect of farmyard manure and of artificials on clover and wheat (grain and straw) succeeding a corn crop.

A good deal of work is being done at Rothamsted and elsewhere to discover the scientific reasons for these various effects and the best way of using farmyard manure, but in the meantime there is another and far more urgent problem, how can the supply of farmyard manure or similar materials be increased?

Two general methods are being studied at Rothamsted. The first consists in reducing the wastage in making and storing farmyard manure, which is very considerable. The second consists in actually increasing the supply of farmyard manure or like substances on the farm, either by keeping more livestock, or by adopting substitutes for farmyard manure. The success attained in the experiments in progress at Rothamsted on the decomposition of straw by artificial means makes it most probable that given a proper air and moisture supply, suitable temperature, freedom from acidity and the addition of the right proportions of soluble nitrogen compounds, a substance resembling farmyard manure can be produced.

Another method of attaining the same object is by the use of green manuring, but for this to be an economic possibility it is necessary to sow a catchcrop after the harvest. Sewage can also be used and an extensive experiment, which was carried out at Rothamsted from 1918-1920, has proved that "activated sludge" gives a fertiliser of high value (1), very considerably better than anything yet obtained. G. A. B.

238 **Physic Nut Cake as a Fertiliser.** See No. 207 of this *Review*.

239 - **The Recent Conference at Rotterdam and the Future Prospects of Nitrate of Sodium.** *Caliche*, Year III, No. 9, pp. 120-131. Santiago (Chile), December 1921.

The difficulty in estimating the consumption of nitrogenous fertilisers during the current season, and the great uncertainty prevailing as to their price, owing to the size of the stocks have naturally had the effect of arresting the anticipated demand. An important conference on the subject was held at Rotterdam on June 20, 1921, which was attended by the representatives of the Association of the Producers of Nitrate of Sodium, of the British Confederation of Ammonium Sulphate and of the German Ni-

(1) See *R.* Sept. 1920, No. 843 (*Fd*)

nitrogen Syndicate respectively. The object of the Conference was to fix the prices of the different nitrogenous products.

It was unanimously agreed that nitrogen consumption could be greatly increased by a better propaganda and by fixing the price. It was stated, as an illustration of this fact, that the consumption of nitrogenous products had been increased 75 % in Germany in 1920, owing to the uniformity of prices, although the cost had risen to double the expected amount. During the same period, the propaganda expenses incurred by the German Nitrogen Syndicate, in Germany alone were more than twice as great as those paid by the Association for the Production of Nitrate of Sodium throughout the world. The possibility of a more energetic nitrate propaganda undertaken in collaboration with the other producers of nitrogenous fertilisers was thus clearly demonstrated and it ought to be equally feasible to associate this important branch of the industry with the production of the two other chief types of fertiliser, phosphates and potash, in order to obtain the full benefit of co-operation. Another point raised at the Conference was the question of establishing an International Credit system similar to that already instituted in Germany which allows of credit being advanced to agriculturists on the value of their crops up to 50 % of the cost of the nitrogenous fertilisers purchased which would greatly increase the consumption of fertilisers to the great advantage of impoverished land. The stock of complete fertilisers in Germany which previous to the War amounted to 450 000 tons of nitrogen as against a consumption of 200 000 tons of nitrogen in the form of nitrate of sodium and sulphate of ammonia has now fallen to  $\frac{1}{3}$  of this figure, but it is believed that by means of active propaganda the farmers can be induced to cover this deficit by the use of sulphate and nitrate of ammonia which would mean an increase of 1 500 000 tons in the consumption of these fertilisers in Germany alone. Long discussions were also held with a view to settling the basis of an agreement between the different manufacturers of nitrogenous products and the suggestion of fixing the price on the markets of consumption at 15 pounds sterling per ton met with unanimous approval, this price being considered quite fair to customers under the present conditions.

The present abnormal situation has had the result in Chili of closing many factories for the extraction of nitrate of sodium; the monthly production has therefore fallen below 100 000 tons, as against an average of 210 000 tons in the preceding year. The Chilean Government regards the situation as one of extreme gravity, for in the nitrate working centres there are already 40 000 men unemployed and if some speedy agreement is not made with the holders up of the stock, unemployment will still further increase. The Chilean Government is evidently following with the greatest interest the negotiations now in progress and has allowed it to be understood that if some agreement is not soon reached, it will be obliged to resume its liberty of action.

Owing to the fall in the exchange and the lower price of sacks and fuel, the cost of production has greatly diminished, being estimated at 6 to 8 shillings per Spanish quintal (46.02 kg.) except in certain isolated cases.

The previous sales at high prices have given the producing societies a solid position which enables them to face the present situation and even if they effect no further sales before 1922, the profits obtained up to December 1921 should leave them well content. The future of the industry is, however, uncertain, but if an agreement can be arrived at between the rival nitrogen producing companies to fix the price at 15 pounds sterling, there would be a sufficient margin of profit to cover present expenses, and more energetic propaganda would also do much to increase the receipts.

To sum up: the nitrate of sodium industry is now passing through one of the periods of crisis to which its market has always been subject, but the present situation may be regarded as temporary and due to the general economic situation, not to a change in the views of the world's consumers of nitrogen.

G. A. B.

AGRICULTURAL  
BOTANY,  
CHEMISTRY  
AND  
PHYSIOLOGY  
OF PLANTS

240 - **Studies relating to the Anatomy and Physiology of the Sugar-Cane in Cuba.** — MAMELI CALVINO, E. (Jefe del Departamento de Botánica de la Estación Experimental Agronómica, Habana), in *Estación Experimental Agronómica, Boletín* No. 10, and *Revista de agricultura, comercio y trabajo*, Year IV, No. 1, pp. 551-555. Havana, 1921.

The author gives an account of the attempts made to secure new varieties of sugar-cane by means of sexual reproduction. He criticises the methods adopted to obtain seedlings (alternate rows; castration of the flowers; self-pollination, cross-pollination with the aid of bags; cross-pollination without protecting the flowers with bags). He describes the varieties "Cristalina", "Uba" and "C 291" and their distinguishing histological characters (epidermis of the internodes, nodes and leaves; siliceous bodies; waxy covering; starch grains, hairs of the auricles and surrounding the leaf-blade). He passes on to speak of the conditions determining the flowering of the sugar-cane and gives a critical review of the results hitherto obtained by experiment from which he draws the following conclusions:

1) The methods hitherto adopted for protecting inflorescences in order to guarantee paternity in crosses between varieties of sugar-cane are insufficient to prevent the possible intrusion of foreign pollen, as such pollen is able to find its way through muslin, and even finer materials. The use of bags of paraffined paper or glass boxes entails the drawbacks of defective air circulation and rise of temperature.

It is necessary in each country to study the protective devices best suited to the local conditions of humidity and temperature. The author suggests the following method as adapted to all Experiment stations where sugar-cane is sown. A greenhouse, either fixed or movable, should be constructed above or below ground in which the crossings can be made by dusting the inflorescences of the female plants with pollen. The plants to be crossed can be grown directly in the greenhouse, or else in the open in pots or boxes, and transplanted into the greenhouse with all necessary precautions, when just about to flower. If movable greenhouses are used, they can be erected over groups of sugar-canes flowering in the field; care must be taken to prevent the entrance of strange pollen, which, however, in this case is comparatively easy.

The fixed greenhouse offers greater security; it can be divided into compartments by fixed or movable partitions, so that many crosses with different varieties can be made at the same time.

By this method all the errors inseparable from the use of bags of material are avoided and it would be possible to undertake accurate researches on the subjects of self-sterility and self-fertilisation under the best conditions for the fertilisation of the sugar-cane.

2) The macroscopic and microscopic characters of the inflorescence though hitherto generally neglected in the descriptions of the different varieties, are of the greatest importance in their identification and also in the choice of the best individuals for crossing.

3) The histological study of the sugar-cane has revealed considerable differences between very nearly related varieties.

4) The conditions causing the irregular flowering of the sugar-cane are at present unknown. It would be necessary to take into account in each district the data relating to the temperature, the hygroscopic state of the atmosphere and soil, the duration of insulations and the light intensity during both the vegetative and flowering periods.

5) In Cuba the sugar-cane usually flowers from December to March, though some varieties may flower to the end of April. At the Havana Experiment Station, there are 18 varieties that have never borne flower. On the other hand the varieties *Cristalina*, and *Uba* from Natal, and a number of seedlings obtained at the Station itself, flower every year. Of these C46 and D99 bore flowers at the age of 7 months.

6) The pollen of the sugar-cane contains a considerable amount of starch from the beginning of the formation of the pollen-grains in the pollen mother-cells, and it only disappears when the pollen-grain is about to pass down into the pollen tube.

7) Pollen grains with no starch are as a rule abortive and morphologically abnormal.

8) Among the varieties grown at the Havana Experiment Station, some have normal pollen in all their inflorescences from December to March; whereas in others the pollen is abortive in the inflorescences of February and March. On the other hand the *Uba* sugar-cane from Natal produced in 1920, inflorescences with abortive pollen from December to March, and one inflorescence with much normal pollen at the end of April.

9) Some of the inflorescences of the same variety coming from different localities may contain normal pollen, while the pollen of the others may be abnormal.

10) Sugar-cane pollen will not germinate in the ordinary cultural media; several different substances were tried, amongst them were the viscous stigmata of the flowers of *Nicotiana Tabacum* var. *havanensis* which proved quite satisfactory.

11) As a result of the microscopic examination of the pollen and pistils of 36 varieties of sugar cane, 20 crosses were made at the Havana Experiment Station, and out of the 100 seedlings produced, 16 bore fertile seed.

12) The seeds of 14 varieties believed to have been fertilised by natural pollinisation were also planted; 8 of the resulting seedlings bore fertile seed which produced 29 plants.

13) From the author's studies it would appear that the presence of starch in the styles, is not a character associated in any way with the fertility of the ovaries, for varieties like C7, C30, C37 and H109, which were found to have no starch in their styles, produced fertile seed both in the case of the naturally and of the artificially pollinated plants.

14) The present experiments of the author in Cuba, shew that the minimum time for the germination of sugar-cane seeds is 3 days, the maximum being 8 to 10 days. As a rule the seeds take 5 to 6 days to germinate in the sterilised boxes for propagation. F. D.

241 - **Notes on the Work of the Phytotechnical Station at Gayerovo (Paraná), Brazil.** - ZEDNECK and GAYLER, C., in *Boletim de Agricultura, Commercio e Industria*, Nos. 1-3, pp. 3-10. Bahia (Brazil), March 1921.

PLANT  
BREEDING

In the selection of cereals, the following characters are taken into account: number of culms; length of culm; length of ear; number of grains per plant; weight of 1000 grains; weight in gm. of the culm, ear, grains, awns, of the second internode of the culm; total weight of grains of a single plant; density of ear; resistance coefficient of the culm and of the 2nd internode; shape of leaves, plant mass.

WHEAT - 400 plants of the Barleta variety were chosen in the first place; of these 11 were employed as heads of lines (mother plants), and the others for mass selection.

As a first result of the latter process may be mentioned Barleta, Paraná, type 1914, which gives a higher yield than the original strain.

In addition to selection work the Station has undertaken comparative cultural experiments with 3 Japanese varieties: Sgatingo, Eshima, Shiro and Shiobaya of which the first is distinguished by its early maturing: it ripens in 3 months only, this is a valuable character under the climatic conditions existing at Gayerovo.

The Station has also made pedigree selections of rye and comparative tests of some varieties of oats, in order to study their rust resistance. Excelsior (from Rio Grande do Sul), is practically immune, whereas the North American types Aurora No. 831, Fulghum No. 408, and Red Rustproof No. 518-3 were severely attacked by the fungus.

MAIZE. - Characters forming the object of examination: vigour of culm; shape of leaves; early maturity; weight of ear in gm; length of ear; circumference of the lower, middle, and upper thirds of the ear; number of rows of grains; number of grains per row; total number of grains per ear; weight of rachis in grammes and in % of whole ear; weight of grains of a single ear; weight of 1000 grains.

Selection work has been begun on Golden Dent, the variety that seems most suited to local conditions, with a view to further improving it and preserving its purity.

The female parents had been the Canipea ear, a prize-winner at the Rio de Janeiro Show, and 4 other ears chosen on the field.

The seed from the Campea ear produced plants that were already clearly superior to all the others. Comparative cultural experiments were also made with *Dr. Assis*, *Brazil*, *Horsting Prolific*, *Gerrick*, *Loveliest* and *Laguna*.

**PULSE CROPS.** — Characters investigated : number of pods per plant ; number of seeds per pod ; total number of seeds ; weight of seeds per plant ; weight of 100 seeds ; disease resistance, etc.

**PEAS.** — From the comparative cultural tests it was found that the most suitable varieties are *Burt's Early*, *Morning Star*, *Prosperity* and *Bliss Everbearing*.

**POTATOES.** — Characters investigated : total number of tubers ; total weight of tubers ; average weight of a single tuber ; mass of foliage and haulms ; disease resistance.

In the variety *Silezia* are found united in the best proportion the 3 characters : high yield, good quality and disease resistance

The selection of this variety was begun on 3 lines, Nos I, II, III.

The French beans, the cotton plant ("Express" variety), and the pea-nut were also made the subjects of experimental researches. The following 4 varieties of the pea-nut were examined : *Indios Nhambiquara* (grown by the Indians of this name), *Parccis* and *Tupis de Matto Grosso*, *Hespanhol Rasteiro*, *Red Pea-nut* and *Gayeroso*. The Indian variety is distinguished by the size of the seeds which are 4 times as large as ordinary pea-nuts.

242 — **Hereditary Behaviour of a Dwarf Form of Barley in Japan.** — MIYAZAWA BUNGO, in *Journal of Genetics*, Vol II, No. 3, pp. 208-208, 20 plates, Cambridge, December 1921

From crossing one individual, "*F<sub>1</sub>* Goldenmelon × Sekitori", with the Goldenmelon parent, 96 offspring were obtained, one of which, a dwarf plant, was interesting as regards its hereditary behaviour.

The characters of this plant together with those of its parents, are as follows :

	Goldenmelon	Sekitori	Dwarf Plant
Height of plant. . . . .	tall	short	less than Sekitori
Rows in ear . . . . .	2	6	2
Length of awns. . . . .	long	short	long
Time of ripening . . . . .	late	early	later than Goldenmelon

Although this dwarf plant tillered more abundantly than normal varieties, over half the shoot, thus developed failed to produce ears.

In November 1915 about 40 seeds of this dwarf plant were sown, and in 1916, 24 plants were obtained, 18 being dwarfs and 6 normal (ratio : 3 : 1). In November seeds taken from 9 dwarf and 6 normal plants were sown ; in 1917 all the normal plants were found to breed true to type.

whereas the offspring from the dwarf plants contained 292 dwarfs and 161 normals (64.5 and 35.5 % respectively).

It is thus seen that:

- 1) The dwarf character is dominant.
- 2) All the dwarfs are heterozygous, for as the ratio of dwarfs to normals is approximately equal to 2 : 1 instead of 3 : 1, it is clear we are not dealing with a typical segregation.

DE VILMORIN has already studied the dwarf forms in wheat and always obtained 2 dwarfs as against 1 normal, so that this result might be caused by the fact that any zygote homozygous in respect of dwarfness is either not produced or dies very early.

The present case is very similar to that described by VILMORIN and in the author's opinion, might be explained by one of 2 alternatives

- 1) Seeds containing zygotes homozygous with dwarfing do not germinate (this hypothesis is excluded by the results of the germination tests);
- 2) Such seeds die soon after germination

In order to test the second hypothesis the author sowed some seeds from dwarf and normal plants in pots and placed the latter in a cold frame to protect them from severe cold. In late April he discovered among these seedlings quite a new dwarf-form (a sterile dwarf), which tillered freely (in some cases 152 shoots to a stock), but grew very slowly and produced no ears; the length of the culms was much less than in the dwarf type mentioned above. By the middle of June all these plants died as a result of the attack of *Erysiphe graminis*, whereas the other two types (the normal and fertile dwarf), had completed their growth.

Out of 323 plants there were: 71 sterile-dwarf, 172 dwarf, and 80 normal, according to the ratio 1 : 2 : 1 (80.75 : 161.50 : 80.75). In the preceding experiments, a certain number of sterile-dwarf plants must have escaped notice owing to their weak constitution which caused them to succumb to the severe cold. In a control experiment made by sowing some seeds of the dwarf plants in the early spring, so as to enable them to escape the winter, 684 plants were obtained; of these 156 were sterile-dwarf, 340 dwarf, and 188 normal, the ratio of the 3 types being approximately 1 : 2 : 1.

CONCLUSIONS. — The dwarf plant found in 1915 at the beginning of the experiments was heterozygous with respect to the character in question and was intermediate externally; *i. e.* shorter than normal, but taller than sterile-dwarf. In other words, if we denote the allelomorph for dwarfness by **D** and its absence by **d**, we have sterile-dwarf = **DD**, normal = **dd** and ordinary dwarf = **Dd**.

243 - **Svalöfs Odal, a New, Early Variety of White Oats suited to North Sweden.** — AKERMAN, A., in *Sveriges Utsäddstidskrift* s, *Fidskrift*, Year XXXI, Part 6, pp. 244-250, fig. 1, Malmö, December 1921

Of late years as regards oats, one of the most important breeding problems in North Sweden, was the method of obtaining a type in which very

early maturity is associated with the valuable qualities found in the Guldregn variety viz., high yield, good quality of grain and strong straw.

A type of this kind was especially needed in districts where, as Guldregn and other varieties had proved too late, agriculturists had fallen back upon inferior white sorts such as Dala and native oats. Moreover where Guldregn is already habitually grown and even in the latitude of the south of Dalarna, cold seasons occasionally spoil the crops which do not ripen properly, so that an earlier variety is desirable also in these parts of Sweden.

For this reason, selection work was carried out on an early oat from North Scandinavia, and the final result was Dala of Svalöf, a white oat ripening certainly a little before Guldregn, but with poor straw and low yield and hence not extensively cultivated

Subsequently NILSSON-LINDEL crossed Dala with Guldregn and by selecting the offspring of this cross, obtained amongst others, O 1163 *b* which was tested and at once put on the market under the name of Svalöfs Odalhavre (Svalöf's Odal). In this hybrid the good characters of Guldregn were associated in the right proportion with early maturity. Odal does not head early, but ripens quickly, so that the interval between the appearance of the panicles and the maturity of the grain is considerably shortened (See Table I)

TABLE I - *Duration of the growth period (in days) for certain lines of Guldregn Dala at Svalöf and at Holm (Ångermannland)*

Sort-	Svalöf 1912-1919		Holm 1917-1920	
	Until heading	Until ripening	Until heading	Until ripening
03861 Guldregn . . . . .	66	108	57	95
01161 from 0386 0924	66	104	—	—
01163 Odal . . . . .	65	104	56	94
0924 Selected Dala. . . . .	67	102	55	90
White oats from the north	—	—	35	90

Thus, as regards precocity Odal ranks between its parents, being earlier than Guldregn, but later than Dala

From the point of view of grain production, it yielded on an average at Svalöf 9 % higher than Dala (average 1912-1919) Odal, 34 12 quintals; Dala 31 04 quintals the best crops were obtained in the good years 1912-1913-1915-1916, whereas in 1914 and 1917, years of severe drought, the yield was somewhat low

Thus the new type would appear to have inherited specifically high productivity from Guldregn, but to have lost, at least to some extent, the capacity (peculiar to Dala) of giving a high yield, even under less favourable climatic conditions

On the other hand, it produces less straw than either Dala or Guldregn, this is due to the shortness of the culms (Odal 41 76 quintals; Dala

45.06 quintals; Guldregn 44.16 quintals). Similar results were obtained at the Sub-Station of Ultuna (Domnarfret territory) as well as in the district of Kopparberg, where Odal proved itself superior to the black oats Björn and Orion, both as regards grain and straw

At the Sub-Station of Varpnas (South Varmland), Odal has surpassed Guldregn two years out of three, and very encouraging results have been obtained in the district of Gävleborg where this kind of oats is being more and more cultivated.

Table II gives the data of a series of cultural experiments made at Holm, in the southern part of Ångermanland.

TABLE II. — *Straw and grain yield per hectare of several types of oats at Holm (Ångermanland) in 1917-1920.*

Type of Oat	Average		Yield as compared with that of Guldregn = 100	
	Grain	Straw	Grain	Straw
0386 Guldregn . . . . .	2948 kg	3920 kg	100.0	100.0
01163 Odal . . . . .	2050	3778	100.0	96.4
0924 Selected Dala . . . . .	2820	3928	95.7	100.0
White Oat of the North . . . . .	2655	3773	90.1	96.4
01163 d of 0386 0924 . . . . .	3313	4273	112.4	109.0

It should, however, be mentioned as regards the data of Table II, that Holm is situated in a very favourable position; therefore it would not be wise to apply the conclusions to all the district of Ångermanland and to the northern part in particular where the duration of the growth period is much reduced.

The introduction of Odal into Vasterbotten must be limited to the most favoured portions of the province. This variety is too late for Jamtland and should not be introduced.

As regards the strength of the straw (resistance to lodging), Odal proved itself distinctly superior to Dala, and nearly equal to Guldregn in the practical tests made at Svalöf (See Table III)

TABLE III. — *Comparative resistance to lodging of Odal and other types of oats.*

Sorts	Degree of strength of Straw 10 = remains quite erect 1 = laid even with the ground	
	1918	1919
0386 Guldregn . . . . .	7	9
01161 c, from 0386 x 0924 . . . . .	—	7
01163 b, Odal . . . . .	6	8
01163 d, from 0386 x 0924 . . . . .	—	8
09241 Selected Dala . . . . .	3.5	5

In its general morphological characters, Odal is very similar to Guldregn; its grain is of fine yellow colour, and is slightly larger than that of Guldregn. Table IV gives the weight per hectolitre of 1000 grains and the % weight of the grains.

TABLE IV. — Characters of the grain in some lines from the cross Guldregn × Dala According to the Data Collected at Svalöf, Domnarvet and Holm.

Varieties	Svalöf 1912-1919			Domnarvet 1913-1919			Holm 1917-1919		
	Weight of 1 hectolitre in kg.	Weight of 1000 grains in gr.	Percentage of grain	Weight of 1 hectolitre in kg.	Weight of 1000 grains in kg.	Percentage of grain	Weight of 1 hectolitre in kg.	Weight of 1000 grains in gr.	Percentage of grain
0386 Guldregn . . .	53.0	30.6	75.3%	54.9	32.6	76.2%	40.5	34.0	73.2%
01161 from 0386 × 0924 . . . . .	50.8	29.4	73.0	52.6	30.9	75.1	—	—	—
01163 Odal . . . . .	50.5	29.7	72.9	51.7	32.8	75.4	40.9	35.1	71.9
0924 selected Dala White Oats from the North . . . . .	50.0	27.2	72.3	51.1	28.7	73.9	41.9	31.4	71.8
	—	—	—	—	—	—	39.4	27.1	67.8

The grain percentage and weight of 1 hectolitre are slightly less than in the case of Guldregn, but higher than in Dala.

From the results obtained, it may safely be said that the object of the selection processes have been to a large extent attained. The aim was to obtain an earlier type than Guldregn, but possessing its excellent qualities. It is true that in this case as in most crosses it was not possible to unite the positive characters in the degree in which they were present in the parent plants.

The result is, however, eminently satisfactory and the new variety can well be used instead of Dala as a substitute for Guldregn in districts where Guldregn has been found to ripen too late.

244 - The Inheritance of the Character "Yellow Striping of Leaves" in the Oat. — CHRISTIE, W., in *Zeitschrift für Indukative Abstammungs und Vererbungslehre*, Vol. XXVII, Part. 2, pp. 134-141, 1 fig. Leipzig, December 1921.

The author in 1914 found in a pure line of oats "Moistad Grenadier" (isolated in 1906), a single plant with well-marked longitudinal yellow stripes on its leaves and even on the glumes.

In 1915 he obtained by self-fertilisation, 8 striped and 2 green individuals. None of the latter bore seed capable of germinating; on the other hand, 3 of the former plants produced offspring forming a total of 24 green and 19 striped individuals (1916).

In 1917 out of the 14 green 1916 plants, 5 had green progeny, and the descendants of the others segregated into green and striped specimens; whereas out of 7 of the striped plants, 2 had striped descendants and the others had both green and striped offspring.

As regards the segregation proportions, these varied greatly from one plant to another : the totals were :

In the progeny of green plants : 302 green and 112 striped.

In the progeny of striped plants : 33 green and 98 striped.

This work was continued in 1919 and 1920

The results obtained during the last year may be briefly summarised as follows :

*Summary of the results obtained in 1920.*

Colour of the leaves of the mother-plants	No. of plants in 1920		Colour of the leaves of the mother-plants	No. of plants in 1920	
	Green	Striped		Green	Striped
<i>Green</i> (constant)			<i>Striped</i> (segregating)		
Total for 66 numbers	1674	—	No 8 . . .	9	11
<i>Green</i> (segregating) .	6	—	" 104 . . .	4	2
Total for 20 numbers	68	—	" 71 . . .	1	—
No 53 . . .	2	2	" 73 . . .	—	3
" 148 . . .	4	2	" 103 . . .	—	2
" 150 . . .	6	11			
Total for these 3 numbers	12	15	Total for these 5 numbers	14	18

The green type therefore only exceptionally splits up into green and striped descendants, and in very variable and indefinite proportions. As a rule the striped individuals out-number the green. Some of the green plants resulting from segregation are fixed, while the others are liable to segregation. The *striped* type can give rise to the *green* by segregation and the green type in turn can produce the *striped*. This phenomenon, together with the variation in the ratios of segregation makes it probable that this character is not Mendelian but similar to that already discovered in other plants by BAUR, CORRENS, and IKENO and MILES.

The author proposes to investigate the matter still further by crossing the striped with the normal type. G. A.

245 - **Inheritance of the Character, Crinkly Leaf, in Maize.** J. MURSON, R. A., in *The Journal of Heredity*, Vol. XII, No. 6, pp. 267-270, figs. 3, Washington, July 1921

From crossing a strain of Dent maize with a strain of flint maize, a type with crinkly leaves was obtained in the  $F_2$  generation. The crinkly individuals are usually about  $\frac{2}{3}$  the normal height, the tassels are relatively short and compact, and not infrequently bear numerous seeds ; often part of the central spike of the tassel is more or less ear-like. The upper leaf-blades are relatively short and broad and frequently have prominent lobes near the base ; the crinkles are perpendicular to the median nerve.

Crosses between normal and crinkly individuals invariably give normal  $F_1$  plants, and in the  $F_2$ , normal and crinkly plants in the 3:1 ratio.

Therefore probably this character of crinkled leaves depends on a single Mendelian recessive factor according to the scheme of a monohybrid. G. A.

- 246 - **A Sectorial Chimera obtained, by Crossing Two Varieties of Maize in India.** — KHADILKAN, T. R., in *The Journal of Heredity* Vol. XII, No. 6, pp. 284-285, 1 fig. Washington, July 1921.

At the farm of the Agricultural College, Poona, crosses were made in 1920 between two varieties of maize known as Canada Red No. 5 and Amber Pearl pop-corn No. 8, one cob being obtained which duly ripened.

Out of a large number of plants grown from the seeds of this cob there was one in the  $F_1$  generation which grew to the height of 6 feet and had one tiller. One vertical half of the plant and of the tiller was normal, while the other presented the following characters.

1) In all the leaves half the lamina bisected by the mid-ribs was normal; the other bearing yellow and whitish stripes.

2) The leaf-sheaths and stem were also striped in the same manner.

This plant is an excellent instance of sectorial chimera which the author proposes to study further in the  $F_2$  generation. G. A.

- 247 - **A Case of Dimorphism in Rice Connected with Segregation Phenomena.** — PARNELL, T. R., in *Journal of Genetics*, Vol. II, No. 3, pp. 209-212, plate XXI, Cambridge, December 1921.

The inheritance of the so-called *glutinous* character which is typical of a small group of cultivated varieties of rice has been the subject of special study for several years. The glutinous type differs from the ordinary *starchy* type chiefly in forming a sticky mass like glue when it is boiled. Microscopic examination of sections of the two kinds of rice shows no marked difference between them, though they are readily distinguished by their colour reaction. The starchy grains when treated with iodine take on the usual deep blue colour, whereas, the glutinous grains become reddish, passing through wine-colour to dark brown as the strength of the solution is increased.

In inheritance, the glutinous character behaves as a simple recessive, but since double fertilisation takes place, the usual complication of results is obtained. Thus, flowers of a glutinous plant fertilised with starchy pollen produce flowers with starchy endosperm. An  $F_1$  plant on being selfed, bears a mixture of starchy and glutinous grains, giving rise in the  $F_2$  to 3 groups of hybrids bearing respectively: 1) all starchy grains; 2) all glutinous grains; 3) a mixture of starchy and glutinous grains. The two first groups remain constant in the  $F_2$  and succeeding generations, whereas the third produces mixed progeny also formed of 3 groups of individuals.

The mixture of grains in an  $F_1$  plant should give a simple 3:1 ratio of starchy to glutinous. In fact on 9 plants, 5292 starchy grains and 1587 glutinous grains were counted (theoretically the figures should have been 5759 and 1720). In the  $F_2$  generation each individual of the three groups

of plants would be expected to give a 1 : 2 : 1 ratio of starchy seeds : mixed seeds : glutinous seeds. In the 81 families so far raised there is a very considerable departure from this ratio in favour of the starchy grains the numbers found being 9211 : 13 729 : 5021, instead of 6990 : 13 980 : 6990 as was expected.

The author has made the important discovery that the  $F_1$  plants have two different types of pollen. One on being treated with iodine, gives the dark blue reaction of ordinary starch, and the other reddish reaction of amylo-dextrine. The pollen of the starchy parent gave the blue reaction and that of the glutinous parent the reddish.

A careful study of the proportion of the 2 types of pollen in the anther (18 anthers from 3 plants having been examined), showed that the proportion of starchy pollen varied from 43.2 % to 51.8 %, the average being 48.1 %.

There can be no doubt that the two types recognisable in the  $F_1$  pollen represent the two genetic types produced by segregation. The author proposes continuing his researches with a view to determining at what stage in spermatogenesis the segregation takes place and considers that this line of work offers distinct possibilities whenever microchemical tests are practicable, especially if such dimorphism can be found in species in which the pollen grains remain united in tetrads.

G. A.

248 - **On the Fixity of Characters in New Hybrid Potatoes.** — SCHRIBAUX, in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol VIII, No 4, pp 81-82, Paris, January 1922

AUMOT, who is continuing his researches on new potato hybrids obtained from seed has found that in certain cases the qualities (characters), of the parents are intensified in the hybrids.

Many of the latter when propagated from naturally fertilised seed have proved very stable.

A hundred individuals belonging to line No. 120 (Beurre  $\times$  Bolivienne 10 bis 1919) possess all the characters of their parents, luxuriant, strong-growing foliage, the shape and pink skin of Bolivienne 10 bis and the yellow pulp of Beurre.

In 1921 when the ordinary varieties produced tubers for the most part unfit for "seed", the hybrid potatoes were entirely satisfactory in this respect.

Some types were wonderfully resistant to the drought and at the same time very productive. The yield of some of the hybrids raised from seed often exceeded 1 kg. per clump; No. 90, the most prolific, produced 1 300 kg. per clump; some of the tubers weighed as much as 340 gm. each.

These results are really remarkable; they are especially striking, because in 1920, some of the hybrids proved to be immune to *Phytophthora infestans*, which shows that it is possible to obtain types uniting superior qualities with resistance to this destructive parasite.

G. A.

- 249 - **Pure Line Selection of the Bundelkhand Cottons in India.** — BURT B. C. and NIZAMUDDIN HYDER, in *Agricultural Research Institute, Pusa, Bulletin* No 123, pp 1-15, Calcutta, 1921

This paper gives an account of a series of pure line selections made with a view to improving the native cottons of Bundelkhand and of obtaining types of better quality able to resist the excess of moisture in years of heavy rainfall.

Three native cottons were selected for detailed study: *Rath*, *Kulpahar* and *Jalaun*. These were evidently populations made up of types differing greatly as regards flower-colour, leaf-shape, habit-quality, of lint etc.

The two first proved a disappointment, but a good selection, eventually known as J. N 1, was obtained from *Jalaun*. It had a staple of 0.85" to 0.90", a ginning percentage of 36 %, and proved very resistant to adverse atmospheric conditions

G. A.

- 250 - **Male-Sterility in Flax, Subject to Two Types of Segregation, Ambilateral and Unilateral.** — BARTON, W., and GARDNER, A. I., in *Journal of Genetics*, Vol II, No 3, pp 261-275, Plate XXIV. Cambridge December 1911

In 1912, a plant of *Linum usitatissimum* was isolated. It differed from the normal type in flowering about 10 days later and its procumbent habit; the stems reached about 2 ft in length, lying at first flat on the ground, turning upwards as flowering begins and finally standing more or less erect.

This blue-flowered procumbent type was fertilised in 1916 with pollen from a tall white-flowered fibre-flax. The  $F_1$  generation was erect and intermediate both in height and colour.

In the  $F_2$  generation the authors found certain plants having more or less completely aborted anthers. The authors were never completely sterile although sometimes little good pollen was produced. From this pollen a few seeds were obtained by self-fertilisation which gave rise to male-sterile individuals only.

Subsequent experience proved that the new form was brought in by the pollen of the common flax, and that the procumbent is genetically hermaphrodite on both the male and female sides. Twenty-four flax-fibre plants of various kinds, when tested, by using their pollen on male-sterile individuals, gave in all 640 plants all with imperfectly developed anthers. To these 24 plants may be added the white-flowered individual (which had been crossed in 1916 with the procumbent type) and a tall blue plant.

From the evidence of these 26 plants it is to be concluded that the fibre-flaxes are generally if not always heterozygous in respect of the male-sterile allelomorph, and that in segregation, this allelomorph is relegated to the male side.

The procumbent type itself is clearly hermaphrodite in genetic composition; by using the pollen of the procumbent type in crosses with normal flaxes, the authors obtained in  $F_2$  hermaphrodite offspring, and from crosses with the male-sterile type, 101 hermaphrodites and 2 male-steriles.

The latter may safely be assumed to have arisen by self-fertilisation the mother-plant not having been emasculated.

When, however, the procumbent type is used as mother,  $F_1$  is hermaphrodite, and in  $F_2$  the male-steriles appear as 1 in 4. It would appear therefore that the female side of the procumbent must be different in constitution from the female side of ordinary flaxes.

In heterozygosis with the female of the procumbent, the dominant factor for anther-development passes with its negative allelomorph to both the male and female organs of the offspring, thus producing an ordinary Mendelian result. When however the negative allelomorph is in heterozygosis with the female side of the common type, it passes wholly to the pollen of the offspring.

The transmission of characters from one side alone (the paternal or maternal), is a matter of great importance from the genetic standpoint. The authors suggest the term *unilateral* for segregation which carries the allelomorph wholly to one sexual side, and *ambilateral* for the segregation which takes place in ordinary Mendelian distribution. G. A.

251 - Contribution to the Study of Bud Variations of Economic Importance in the Sugar Cane. -- BARKER, F. F., in *The Journal of Heredity*, Vol. XII, No. 6, pp. 171-174, fig. 1, Washington, July 1921.

After speaking of the frequent occurrence of bud-variation in the sugar-cane, especially as regards a superficial character like colour, the author dwells upon the importance of making a systematic study of qualitative characters such as sugar content etc., which can only be detected by chemical analyses and experimental tests.

Certain strains of "Cristalina" differ from one another in height and cane-diameter, and consequently in yielding power. Thus cane fields, even though carefully planted for a single variety, may include more than one strain differing in season of maturity, sugar content of juice and other important economic characters which will affect the financial returns.

As to differences in resistance to disease, there are many noteworthy examples. Yellow Caledonia, Cavangire and Demerara 625 resist the so-called "root-disease" comparatively well, while Otaheite and many others succumb to it. Otaheite, Calancana, Cristalina, and Rayada are most susceptible to gummosis while Yellow Caledonia and Cavangire are strongly resistant, perhaps immune to it.

Otaheite is much injured in Australia by the ravages of the white grub and suffers from the disease known as matizado (mosaic), to which Uba and others of the North Indian type of canes are immune. G. A.

252 - Breeding Experiments with Roselle, *Hibiscus Sabdariffa*, in India. - See No. 227 of this Review.

253 - The Possibility of Determining the Value of Seed by Biochemical Means. -- NEMEC, A., and DUCHON, P., in *Comptes rendus de l'Académie des Sciences*, Vol. 173, No. 20, pp. 933-935. Paris, November 11, 1921.

The authors have studied the relations between the vitality of seeds and their diastasic activity with a view to ascertaining the possibility of

determining the agricultural value of seeds (especially their germinating capacity and energy), by a rapid and at the same time easy, biochemical method offering greater advantages than the germination test which is sometimes a lengthy process, lasting 5 to 30 days (seeds of forest trees), according to the species.

They have investigated the relations of the various diastases (amylase, invertase, glycerophosphatase, lipodiastase, urease, uricase, phytoprotease and catalase of seeds), to the vitality of seeds of different species (maize, white mustard, soy-bean), varieties, and origin.

The results have shown that the action of hydrolysing diastases can survive the germinating capacity of the seed. The catalase behaves in a totally different manner; it would seem that the lost vitality of the organism is intimately connected with the impaired activity of the catalase. It is well-known that this enzyme is extremely sensitive to the hydrogen ion; possibly the chemical changes taking place in the seed, which are characterised by the progressive acidification of the organism, bring about the gradual cessation of the activity of the catalase; in dead seeds this activity seems to be almost completely at an end. The small amount of oxygen released in this case may be attributed to the action of mineral catalysts or to the colloidal substances present in the seed.

It is evident, that the activity of the catalase, as measured by the cubic centimetres of oxygen liberated, affords an excellent means of quickly and easily determining the agricultural value of seeds. The estimate can be made in a few minutes. It only now remains to fix the limits for the practical application of this vital test.

**CEREALS  
AND  
PULSE CROPS**

254 - Varieties of Wheat Cultivated in the Province of Cagliari, Sardinia. - BLANDINI, F. (R. Cattedra Ambulante di Agricoltura di Cagliari), in *l'Italia Agricola*, Year 58, No. 12 pp. 309, 1 coloured plate. Pissanello, December 15, 1911.

The Miocene soils of Trexenda and Marmilla, the alluvial soils of Campidani and Sulcis and the Plateaux of Planargia and Sarcidano, which form the chief wheat-growing areas of the province, produce hard wheats equal in quality to any in the world. Soft varieties are, however, little known, for the few that have been imported ended by becoming hard wheats as a result of the climate, soil and natural intercrossing with the local types.

The Sardinian peasant prefers hard wheat to soft, as it is less inclined to shed its ears or its grain, which allows the harvesting to be protracted, which is a great advantage in a relatively sparsely populated region with 25 inhabitants to the square kilometre, of whom only 6 to 7 are peasants.

The variety that best meets the requirements is "trigu murru" (whitish wheat). It is in fact grown on  $\frac{4}{5}$  of the wheat area of the province. Afterwards come in descending order, "trigu biancu" (white wheat), "trigu arrubiu" (red wheat) and "trigu moru" black wheat.

TRIGU MURRU. - This variety, when sown from the second fortnight of October to the end of December, according to the season, ripens the first fortnight of June on the coast and in the Campidani, and in the last fortnight of June, or the first fortnight of July, in the hill zone and on the plateau.

It is resistant to lodging and tillers freely: 75 to 80 kg. of seed are planted per hectare.

This wheat is especially adapted for macaroni etc.

Its characters are as follows: ear rectangular, awned, blackish-yellow, 23-25 fertile, closely-growing spikelets.

Spikelets with 3-4 fertile flowers.

Glumes oval, lanceolate, with sharp strong keel; terminates in a short pointed beak, black spots on the edges.

Palea, oval, inflated, terminating in blackish-red awns, that fall off at maturity in favourable seasons, but are otherwise persistent. Seeds oval, slightly convex, pointed, of a fine wheat colour and with straight central section.

Average length 8 mm., breadth 2-5 mm.

Culms full throughout their length, strong.

256 - **Mansholt III, a Variety of Oats Resistant to Lodging.** — DESPRLZ L' (Directeur de la Station expérimentale agricole de Cappelle, Nord), in *Journal d'Agriculture pratique*, Year 1, No. 3, p. 107, Paris, February, 1922

The author reports the very satisfactory results he has obtained with Mansholt III. This variety of oat was obtained by selection from Victoire de Svalöf by Prof. MANSHOLT of the Royal Netherland College of Wageningen (Holland).

Its chief characteristics are: fairly short, very thick, stiff straw, with panicle; white, plump grain like that of the Victoire variety, but distinctly larger; matures early ripens well in good seasons, the weight per hectolitre is 52 to 53 kg. As Mansholt III does not tiller it must, be sown closer.

"It is an excellent oat, very resistant to lodging; it should not be grown on poor, light soils, but it is very suited to rich, liberally manured land".

F. D.

257 - **The World Production of Soya.** — *Osten-Verden in Ostasien*, Year VI, No. 22, p. 254, Amsterdam, November 22, 1921

The most recent returns for the world's production of soya are as follows (in tons): China 3 352 400; Japan 430 933; Corea 348 000, United States 58 000; total 4 189 333 tons.

In 1918, Japan absorbed 77% of the Chinese production, America and Europe 7%, China 16%.

In 10 years the soya oil exported from China has risen from 25 000 tons to about 400 000 tons. Before the War, this oil was sent to England, the United States, Belgium, Japan, and Russia. During the decade, the exports of soya-cake has increased from 400-500 tons to over 1 million tons.

258 - **Forage Production in Southern France and North Africa.** — TRUBET, L., in *Le Progrès agricole et viticole*, Year 38, No. 43, pp. 300-308, No. 44, pp. 425-428, No. 45, pp. 451-453, Montpellier, October and November, 1921

In the opinion of the author these regions could become stock-breeding centres, for they possess a climate that is favourable to the rapid and

FORAGE  
CROPS

luxuriant growth of many species of plants and renders it possible to dispense wholly or at all events to a large extent, with stabulation, greatly to the advantage of the health of the cattle.

As a result of experiments carried on for 25 years, TRABUT is able to state that all the best forage plants that would be useful in Southern France and North Africa have by no means as yet been introduced or exploited to their fullest extent. The family of the Gramineae can furnish a very large number of species suitable for stock-feeding and capable of growing in very different climates. The author in his rapid review especially mentions the following ;

*Maize*: innumerable forms of this cereal are cultivated ; it would be necessary to choose the best type for each farm ; selection might be of great assistance in this respect.

*Euchlaena* or *Rcana*, known under the name of " Teosinte " a genus nearly-related to maize giving abundant and excellent forage. As the seed is rare and expensive, this plant is not generally grown, but it thrives in the French colonies, and its production might be increased. On irrigated soils, the Teosinte tillers well ; the amount of seed used is relatively small.

*Tripsacum*. This genus, which came from Central Africa, furnishes perennial forage plants giving a high yield " Zacate prodigio " on the poorer soils of Mexico and Cuba. *Tr laxum* is still under observation in Algiers. *Tripsacum* can fertilise Teosinte and the resulting hybrid is exactly similar to *Tripsacum*. A plant of this section that might prove interesting is *Coix Lacryma-Jovis*, var *Mayuen*, in the Far East, it is grown under the name of " Adlay " and bears soft seeds used as a cattle feed, the straw is plentiful and forms an excellent forage.

Among the different species of *Saccharum*, the Japanese cane grows easily from slips and shoots vigorously throughout the summer until the first cold sets in. In 1920 it yielded 140 tons of forage per hectare at the Ferme Blanche. This plant needs irrigation but can stand a considerable amount of salt in the soil.

*S biflorum* quickly attains the height of 3 metres. It supplies a tough forage which is chopped is readily eaten by stock, but it is improved by being made into silage. This plant is propagated by cuttings 30 to 40 cm in length which are planted in the sand in the spring or autumn. It would be suitable for dunes and a good paper can be made from it.

*Mischantus* (*Fulalia*), a perennial propagated by cuttings, makes good forage. *M. condensatus*, a Japanese variety, produces heavy crops at the Experiment Stations in Algeria.

The forage sorghums are very numerous. Sudan Sorghum (*Sorghum exiguum* Forsk), has slender stems and makes good hay ; it resists drought well and will produce large crops in summer without irrigation. This plant is also eaten fresh and may be mixed with soya. It requires a certain amount of heat ; must not be sown before April ; tillers well ; 15 kg. of seed per hectare sown in rows are sufficient. *S. exiguum* can be crossed with the other cultivated sorghums but the hybrids, though yielding larger crops, are coarser. Hence it is better to use *S. exiguum*

for hay, and feed the hybrids to stock fresh. Sorghums contain a small amount of hydrocyanic acid ; the glucoside giving rise to it disappears at the flowering season and when the plant after cutting has wilted for lack of water. The author has never heard of any bad effects following the use of *S. exiguum* and under favourable conditions this crop can last for several years.

The *Paniceae* tribe supply a large number of forage species suitable to hot and somewhat arid countries *P. molle*, *P. maximum* and *P. miliaceum* may be mentioned.

The different varieties of *Paspalum*, plants native to America, make excellent forage (*P. virgatum* and *P. dilatatum* where the soil is damp). A few tufts are sufficient to insure its spreading without any fear of invasion. Two cuttings of hay can be taken or the field grazed winter and summer.

The various species of *Setaria* (Italian millet, Moha), are very common. The very drought-resistant types from S. Africa and America have yet to be studied. The genus *Pennisetum* has long been known. Two perennial African species are very productive and make excellent forage : *P. purpureum* and *P. Merkeri* (propagated by the Botanic Service of Rhodesia). Most satisfactory results have been obtained from them in Algeria, their crops being much heavier than those produced by the various kinds of maize and sorghum.

*P. purpureum* is sterile and is propagated either by fragments or cuttings. A cutting planted in April throws up 50 stems over 3 metres in height by October. Thus the plant is propagated very rapidly. The cutting consists of a piece of the stem with an eye ; it is put into the ground obliquely.

*P. purpureum* requires much water and heat. In Cuba, 500 tons per hectare of excellent forage have been obtained from it. The crop at Algiers may be estimated at 250 tons. *P. Merkeri* can be grown without irrigation.

*Leersia hexandra* which belongs to a genus nearly related to rice and grows wild in North Africa, does well on the banks of rivers or streams. Under the same conditions *Zizania aquatica* produces a heavy forage crop, As its seeds are difficult to keep, the better plan is to plant a few specimens which spread rapidly.

The *Phalaris* are very plentiful throughout the Mediterranean region and often constitute the basis of the forages. *Ph. stenoptera*, of Australian origin and doubtless a hybrid, is an important member of the tribe. It attains a good height, is rust resistant and forms an excellent spring forage being much superior to the native varieties.

The *Agrostis* can be cultivated on damp clay soils.

Excellent results could be obtained from carefully selected varieties of *Phleum*. *Oryzopsis miliacea*, or *Milium multiflorum* is a perennial producing much seed, it stands a high degree of salinity in the soil, is drought resistant and yields 20 to 30 tons per hectare (in several cuttings). *O. Thomasii* a stronger species which can be used associated with *O. miliacea*, grows on the Côte d'Azur.

*Avena sterilis* is hardier than *A. sativa* and does well in southern countries. Algerian oats tiller freely and when mixed with Alexandrian clover, form a forage of the first quality in winter and spring.

*Cynodon dactylon*, the Dog's-tooth Grass can be propagated in the sands; *Chloris Gayana* is however the more satisfactory; it is an African species with a very extensive area (from Tunisia to Rhodesia). This variety of *Chloris* is a perennial; it puts out long stolons that run along the surface of the ground and send down roots at the nodes. Light soils suit this plant best. *C. Gayana* produces a large crop of excellent forage and can be extirpated from any ground it has invaded.

The *Eleusineae* produce large forage crops and bear much seed.

Among the *Festuceae*, *Festuca elatior*, a wild variety, takes the first place. The author reports *F. pratensis* from the northern districts, *F. arundinacea* from the southern and *F. Fenas* from the salt steppes.

*Bromus unioloides* (Schrader's Brome-Grass), an American variety, produces early forage and stands until the autumn.

In Australia small-seeded wheats (Lambrig) are used for forage.

The many forms of *Lolium* yield good forage. Heavy crops can be obtained in the southern regions from the Leguminose which should be grown in association with the Gramineae. P. C.

259 - A New Fodder Grass from Uganda, *Pennisetum polystachyum*. — In *Bulletin of the Imperial Institute*, Vol. XIX, No. 3, pp. 295-296. London, 1921.

The grass identified as *Pennisetum polystachyum* Schult. recently submitted to the Imperial Institute, London, for examination with reference to fodder value consisted of plants of pale greenish-straw colour, from 26 to 45 in. long and bearing immature seed heads. The material contained 7.4 % of moisture. The percentage composition is shown as follows, expressed on the moisture-free material, in comparison with the corresponding figures recorded for elephant grass (*P. purpureum*) and timothy grass (*Phleum pratense*).

The sample was found to be free from cyanogenetic glucosides.

From the above figures it may be noted that the *P. polystachyum* grass from Uganda contains a slightly higher percentage of protein than that

	Crude proteius	Fat	Carbo- hydrates (by dif- ference)	Fibre	Ash	Nutrient ratio	Food units
<i>Pennisetum polystachyum</i> . . . . .	9.9 %	2.7 %	38.6 %	40.1 %	8.7 %	1 : 4.5	70
<i>P. purpureum</i> . . . . .	10.5	1.5	41.4	38.8	7.8	1 : 4.3	71
<i>Phleum pratense</i> . . . . .	7.6	0.8	45.3	38.7	7.6	1 : 6.2	66
	8.1	3.1	52.6	30.7	5.5	1 : 7.4	81

present in timothy grass and also compares satisfactorily with *P. purpureum*. M. L. Y.

260 - Cultivation of Lucerne in the Monsoon Districts in India. — See No. 227 of this Review.

261 - **Alfalfa Production under Irrigation (1) Experiments in the United States and in New South Wales.** — I STEWART, G, Alfalfa production under irrigation in *Utah Agricultural College Experiment Station, Circular No. 45*, pp 3-48, tables VII, figs. 13. Logan, Utah, May 1921. — II HARRIS, F S, and PITTMAN, D W, The irrigation of alfalfa, in *Ibid. Bulletin 80*, pp. 3-30, figs. 2. Logan, 1921. — III. CHOMLEY, F G and CHAFFEY, F. A., Producing Lucerne Hay under Irrigation, in *Dept. of Agriculture New South Wales, Farmers' Bulletin No 143*, pp. 3-22, figs. 19 Sydney, Oct 1921

I-II. -- Field and tank experiments on the irrigation of alfalfa were conducted at the Utah Experiment Station, U. S., and apart from the general methods of cultivation employed which are described in detail the following results are worthy of special note.

The best results were obtained when irrigation water was applied in 3 to 5 heavy applications on loams or clay loams, but in 4 to 10 frequent, light applications on porous soils. In these experiments the yield generally increased as the total amount of water applied increased up to 90 acre-inches (the highest amount applied), but the gain in yield from the application of more than 30 acre-inches was too small to pay for the extra labour; 25 in. applied in weekly quantities of 2.5 in. gave better results than 30 in. where 5 in. was applied each alternate week. With an equal amount of water, frequent moderate applications gave better yields than fewer heavy ones.

Where irrigation was not practised, 55 % of the entire yield came from the first cutting and 14 % from the third. Where regular quantities were applied each week, from 33 to 37 % of the crop came from cutting I, from 37-39 % from cutting II and from 25 to 30 % from cutting III.

The relative yields of the different cuttings were to a certain extent changed when the water was applied at various times; but this did not affect the total annual yield consistently.

Apparently the yield was highest when the soil moisture content was kept constantly at 25 %

III. — Alfalfa growing for hay has for some years become a feature of some importance on the Yanco Experiment Farm in New South Wales, and so profitable that the area has been considerably extended; there are now 120 acres under crop with an average of 6 or 7 cuts per season. Speaking generally, one irrigation for each cut has been found sufficient in the early part of the season, but later an average of two per cutting. Irrigation takes place a week before cutting; a second watering is given as soon as the hay is taken off. A big body of water is never turned on the alfalfa at one time. The head ditch is filled and then a gap is opened in the bank about half way between the check banks, allowing enough water to escape to spread from bank to bank, just covering the surface and moving forward very slowly. It should take from 6-8 hours for the water to reach the lower end of the block 6 chains away, by which time the water can be shut off at the upper end. This method is adaptable to heavy soil but on lighter

(1) See R Aug. 1917, No. 813; R May 1918, No 507; R Oct. 1918, No. 1082; R. May 1920, No. 496. (Ed.)

soil, the flow can be somewhat faster. It is considered imperative that facilities be provided for thorough surface drainage, as water lying on alfalfa for 3 hours on a hot day will do irreparable damage to the stand

Apart from the details with regard to irrigation methods employed in New South Wales, the authors give an interesting description of the hay machines etc used, and certain cultural details. M. L. Y.

262 - **The Chemical Composition of Mangolds. Analyses Made in New South Wales.** - RAMSAY, A. A., in *The Agricultural Gazette of New South Wales*, Vol XXXII, Pt II, pp 819-821, Nov 1921

Results of analyses made at Grafton Experimental Farm, Glen Innes Experiment Farm and Hawkesbury Agricultural College, Richmond.

An average of the total analyses made in connection with the recent trials in New South Wales shows the mean composition of the mangold to be as follows: % moisture, 92.01, albuminoids, 0.99; ether extract, 0.04 fibre, 0.77, ash, 1.37, nitrogen free extract, 4.80

According to the comparison table showing the ranges in variation of composition for all the varieties grown at the 3 different State institutions, and those of English mangels, the ranges in the percentage composition are apparently much greater in the mangels grown in New South Wales. The percentage composition of the dry matter content is also very variable, e.g. albuminoids 7.41 to 22.26 %, ether extract 0.16 to 0.99, fibre 2.28 to 18.86 %, ash 6.74 to 36.38, nitrogen free extract, 32.04 to 83.40 %

An interesting aspect of the investigations has been a consideration of the variation between the average composition of 8 selected varieties of mangels grown under widely differing conditions, and on the other hand, of the variation when grown alongside one another at any one of the farms. A similar comparative variation is noted as regards the percentage of dry matter content of these 8 varieties shown as follows

M. L. Y.

263 - **The Decline in the Yield of Egyptian Cotton and its Causes** (1). — DUNGEON, G. C. (lately Consulting Agriculturist to the Government of Egypt), in *Bulletin of the Imperial Institute*, Vol. XIX, No. 2, pp. 160-174. London, 1921.

In this article attention is drawn to some points which seem to have been generally overlooked, and to correct as far as possible some conclusions which appear to have been formed on insufficient grounds.

A survey is made of the existing state of affairs in Egypt as regards the cotton areas and the yields of former as well as of recent years. With regard to the depreciation in the last 7 years, so many new and unforeseen influences have affected the cotton crop that it is considered hardly possible to regard the conditions as in any way normal. The factors influencing the yield per acre are however considered to fall under 3 important headings and are discussed in the following order: —

1) DETERIORATION OF THE PRODUCTIVE POWERS OF THE SOIL IN COTTON-GROWING AREAS. — a) *Excessive cultivation*. — It is an accepted maxim among Egyptian cultivators that the correct rotation of their crops admits cotton cultivation once every three years *i. e.* only  $\frac{1}{3}$  of the cotton growing area or approximately 1 500 000 feddans (2) should bear the crop each year. On reference to the tables it may be noted that from 1905 to 1920 (with the exception of 1915 to 1918 owing to war conditions) this ideal figure had been regularly exceeded, sometimes by as much as 10 % for the whole of Egypt. Consequently the soil ingredients were drawn upon unevenly and the balance of fertility was upset. The fault lies in the fact that advantage has not generally been taken to apply the remedy when the opportunity presented itself, and the recent insuperable difficulties as regards the obtaining of manure.

One of the chief incentives to the practice of excessive cotton cultivation has been the custom of leasing land to tenants on short terms of 3 years. This has been a source of great competition among applicants, and the highest rents are paid to landowners who permit the greatest amount of cotton to be cultivated within the period of the lease. The tenant, having no interest in the land beyond the term of his tenancy, extracts all the cotton possible during that time, but does not attempt to re-establish the fertility of the land for his successor.

This deterioration caused by excessive cultivation could, however, be duly rectified, were it not that other noxious influences have been affecting the soil at the same time.

b) *Rise in the Water Table in the Delta* (3). — The years in which the cotton production was at its highest were those in which the water-supply was limited by the amount which could be carried by the deep canals, and owing to this limitation the soil drained into the canals when their flow was shut off, and in consequence, did not become sodden. After

(1) See *R.* July 1913, No. 801. (*Ed*)

(2) 1 feddan = 1.038 acres. (*Ed*)

(3) See *Movements of Soil Water in an Egyptian Cotton Field*, *R.* Dec. 1913, No. 1323. (*Ed*)

the Assouan Reservoir began to be drawn upon, much more water became available for irrigation, but the canals ran at a higher level, rendering most of the area to which water had previously to be lifted by great exertions what is termed "free-flow" *i. e.* where, by merely opening a sluice the water runs by gravity on to the land water-logged. The injurious effect on growing cotton was evident. Firstly, the use of water above the root system caused asphyxiation of the roots and produced flower and boll shedding and not infrequently premature death. Secondly, lack of adequate drainage caused a return of noxious salts and the toxic effect was obvious. (1)

The establishment of proper drainage will be gradual, and in certain cases, perhaps unnoticeable for some time, owing possibly to the formation of a condition in the soil similar to «hard-pan» for which additional expedients must be employed to restore fertility.

c) *Insufficient supply of manure and fertilisers, and the introduction of noxious substitutes* — This is largely due to the unremunerative results obtained with cattle-breeding, and the consequent shortage of farmyard manure

2) RAVAGES OF INSECT PESTS — The necessity of legislation concerning the pink bollworm (*Gelichia gossypiella*) is a matter of distinct importance (2) The measures instituted to meet the ravages of this new pest are such that, when fully in force a diminution of its numbers may be expected, and as this result implies a retarding of the period of maximum severity, the cotton plants will have a greater opportunity of maturing their late-formed bolls with less injury and of thus increasing their yields.

3) AGRARIAN DISTURBANCES — A short discussion as to the effect of political disturbance etc on the financial situation with regard to cotton

265 — The Cultivation and Production of the Olive Tree in Spain. — (3) MATONÀ, A. (Director of Olive cultivation in Catalonia), in *Revista olearia italiana* Year XII, Nos 9-12, pp 144 148, Rome, September-December, 1921

The author shows the progress made in olive-growing and the olive-oil industry in Spain, and emphasises the advantages that would accrue if the Spanish and Italian manufacturers could arrive at some mutual agreement regarding the improvement of the industry and the better utilisation

(1) See *Egyptian Scientific Journal*, Vol II, p 413, and Vol V, p 190, dealing with the salt-content of some agricultural drainage waters of Egypt. This shows that where a high water table and no drainage occurred there was a concentration of injurious salts in the surface soil causing it to become useless for cultivation (Ed)

(2) See *R* April 1921, No 388 (Ed)

(3) See Prof Manuel PRIRGO's Original Article Olive Growing and Production in Spain, in *R* Dec 1916, pp 1727-1733 (Ed)

of the product. He gives the following data respecting the conditions of olive-growing in Spain.

According to the statistics of 1920-1921, the area under olive-trees is 1 571 294 hectares. It is continually extending and in 1907 the olive yards occupied only 1 353 196 hectares. Olive-growing has increased markedly of late years and owing to the high price paid for olive-oil, agriculturists have transferred their preference from the vine to the olive-tree. The methods of cultivation are not altogether perfect in Spain, but it must be allowed that they are quite as good as the average methods followed in Italy. In some regions, such as a large part of Catalonia and of Aragon, and certain districts of Andalusia, fairly systematic and successful methods are adopted.

In the South specialised olive-yards are preferred. Andalusia and Estremadura are the typical districts of the large, Spanish country estates, some of which occupy 30 000 ; 40 000 ; 50 000 and even 60 000 hectares, and it is easy to find there olive yards of several hundred hectares.

In Catalonia on the other hand, where the land is much subdivided, olive-trees are often grown in association with the almond, carob, hazel and vine, or herbaceous crops.

Although some books speak of the irrigation of the olive-tree in Spain, it can fairly be stated that it is only practised in areas of very limited extent. The land capable of irrigation is naturally reserved for other more suitable crops, and the olive-trees that happen to be associated with them benefit by the water supplied.

Olive production has increased with the extension of the cultivated area, and owing to considerable improvements in the methods of cultivation in certain regions, as is shown by the appended Tables.

The industry of preserving olives uses about 350 000 quintals of the fruit annually, viz : 390 197 quintals in 1914 ; 364 456 quintals in 1916 ; 477 737 quintals in 1918 ; 315 930 quintals in 1920.

The finest oil is made chiefly in Catalonia, in the part of the Province adjoining Aragon, at Toledo, and also in some districts of Andalusia. At the present time, it is true that good oil is found more or less everywhere as there are many oil-factories, but the true oil for exportation which is highly prized by the French and Italian merchants, is the Catalanian product coming from Borges, Reus and Tortosa, and also that from Alcañez (Aragon).

It must be allowed that as a rule, the manufacturing process in Spain is on the same level as in Italy, although in certain regions it is defective owing to the use of superannuated apparatus and old fashioned methods. There are however entire regions of great extent where the plant and treatment leave nothing to be desired and olive oil is produced with an acid content below 0.5 %. Of the 500 000 quintals of oil annually made on the average in Catalonia, at least  $\frac{2}{3}$  are of a fine quality suited for exportation. In this Province the fresh or recently-gathered olives are usually but little handled and the oil is extracted without the use of hot water, by being subjected twice in succession to severe pressure. Not infrequently the oil

coming from the presses is very rapidly washed in order to free it more quickly from the water of vegetation.

Of recent years, the co-operative oil-factories have greatly developed especially in Catalonia, and hence the improvement in the quality of the output. At the present time there are 30 factories in this region producing some 50 000 quintals of olive-oil. The three or four largest factories each handle some 200 quintals of olives. Their plant and methods are thoroughly up to date.

TABLE I. — *Production of Olives and Olive-oil in Spain during the Period 1908-1920.*

Years	Olives quintals	Olive-Oil quintals

The great variations between the output of oil in different years are due to the spread of diseases or of parasites. The most formidable of the latter in Spain, as elsewhere is the Olive Fly (*Dacus oleae*) Meig. As a means of control efforts are now being made to popularise the LOTRIONTE method which was widely tested in Catalonia in 1920.

266 - Illipe Nuts of British North Borneo from *Shorea stenoptera* and other Dipterocarps. — *Bulletin of the Imperial Institute* Vol XIX, No 2, pp 140-142. London, 1921.

The "illipi" nuts of British North Borneo are quite distinct from those of India which are obtained from species of *Bassia* (Nat. Order. Sapotaceae). A full account of the different forms of the Borneo nuts derived from various dipterocarp trees, with the results of examination at the Imperial Institute is given in a previous publication (*Bulletin of the Imperial Institute*, Vol. 13, No. 3, pp. 335, 1915). Since then a quantity of kernels have been forwarded recently for investigation and the results are here given. The kernels were stated to have been obtained from nuts collected in the Kinabatangan district and washed in sea water.

The kernels were found to contain 6.9 % moisture, and to yield, on extraction with light petroleum, 44.8 % of fat, corresponding to a yield of 48.1 % from the moisture free kernels. The fat was a greenish-yellow solid with a faint odour and on examination gave the following results:— specific gravity at 15° C, 0.8551; refractive index at 40° C, 1.456; solidifying point of fatty acids, 52.5° C; melting point of fat 34° C, acid value 11.4; saponification value (mgm. of potash per 1 gm. oil) 192.4; iodine value % 32.2, unsaponifiable matter % 0.6; volatile acids, soluble 0.1 and insoluble 0.4 cc. of decinormal alkali required to neutralise acid from 5 gm. of oil. A comparison is made with the results obtained with a previous sample of illipe fat and with figures previously recorded for Borneo tallow.

The residual meal left after the extraction of the fat from the kernels was yellowish brown and had a faint bitter taste. The results of analysis are as follows: % moisture 11.9, crude proteins 10.3, fat 7.8, carbohydrates etc (by difference) 64.5, crude fibre 3.2, ash 3.3, nutrient value 1: 8.0 and food units 110. (A comparison is given of figures recorded previously for illipe cake").

The meal contained no alkaloids or cyanogenetic glucosides.

These kernels represented the brown variety and contained 48 % of fat in the dry material, which is about the usual yield.

It is stated that in spite of the somewhat low percentage of protein (11.3 %) in the residual meal which renders it a less valuable foodstuff than palm-kernel cake (16 %), the illipe meal has already proved its value commercially.

267 - The Value of the Oil of the Physic or Purging Nut (*Jatropha Curcas*) and Utilisation of the Residual Cake as Manure. — *Bulletin of the Imperial Institute*, Vol XIX, No 3, pp 288-291. London, 1921.

The evergreen shrub *Jatropha Curcas* Linn. (N. O. Euphorbiaceae) is indigenous to South America but has been introduced into most tropical countries. Apart from the purgative and emetic properties of the oil obtained from the seeds and its utilisation for soap manufacture (a fact proved at Lisbon on receipt of seeds from Portuguese Africa), suggestions have also been made as to its possible value as a lubricant to replace castor oil.

Seeds from South Africa and the Gold Coast were examined at the Im-

perial Institute, London, and consisted respectively of shell 39 and 33 %, kernel 61 and 67 %, moisture in seed 7.9 and 11.1 %, yield of oil 31.9 and 33 % and yield of oil expressed on dry seed, 34.6 and 37 %.

An analytical comparison is made between these oils and oil from Nigerian seed examined previously (*Bulletin of the Imperial Institute*, 1904, Vol. 2, p. 170).

To test the value of curcas oil as a lubricant, viscosity tests were carried out with the oil samples and an interesting comparison is made with a commercial sample of castor oil as follows (viscosity in seconds for 50 cc. at 70° F): Gold Coast sample 1; 298; sample 2; 290; South Africa 284, castor oil 3888.

All these samples were also exposed in thin films on glass under varying conditions and according to the results obtained, it is evident that curcas oil differs widely in viscosity and drying properties from castor oil and dried more rapidly when exposed to high temperature and to light and air. For certain types of machinery therefore for which castor oil is particularly suited as a lubricator, curcas oil could not be used with advantage.

Examination of the residual oil cake sent from Zanzibar, prepared from undecorticated seed proved on analysis that the cake has a high value as a manure, being approximately as rich as castor-seed cake in nitrogen and phosphoric acid. It is suggested that the ash obtained on burning the cake would form a valuable concentrated manure, or the potash might be extracted and utilised locally for soap-making. The following percentage composition was determined: moisture 10.4, nitrogen 3.2, phosphoric acid 1.4, potash 1.2, soda 0.21, chlorine 0.13, sulphuric acid 0.08, ash 5.6. The ash contained: phosphoric acid 25.7, potash 20.7, soda 3.8, chlorine 2.4, sulphuric acid 1.5.

In consideration of the fact that the residual cake or meal has purgative properties and could not be utilised as a feeding stuff, but only as a manure, it would doubtless realise a relatively low price. M. L. Y.

#### SUGAR CROPS

270 - **The Qualities of Java Seedling Sugar Canes and suggested Introduction into Louisiana U. S. A.** - CROSS, W. E., *Revista Industrial y Agrícola de Tucuman*, Vol. XI, Nos. 9-10, pp. 118-121, Buenos Ayres, 1921, and in *International Sugar Journal*, Vol. XXIII, No. 265, pp. 614-616 London, Nov. 1921.

The seedling varieties under discussion were produced in Java by crossing the Cheribon cane with the variety Chunnee which grows freely in northern India under generally adverse conditions. These hybrids POJ 36 and POJ 213, combine the qualities of the two parents, being rich in sugar like the Cheribon and very vigorous and highly resistant to disease and frost damage like the Chunnee. For sub-tropical conditions, they are among the best varieties at present known.

It has been noted that although Louisiana U. S. possesses more favourable conditions for cane cultivation than Tucumán (Argentina), only one-year ratoon crop is obtained and it is necessary to practise a rigorous system of rotation, ploughing under leguminous crops one year in every three. In addition to this, considerable quantities of commercial fertilisers have to be applied. — Tucumán on the other hand obtains ratoon crops up to 6 or 8 years, gives little or no attention to the question of crop rotation, uses no fertilisers and obtains with the Java seedling canes better yields of cane and sugar than is generally the case in Louisiana. It is therefore recommended that Louisiana planters might introduce and study these seedlings to their commercial advantage. A summary is given of the qualities of the two Java seedlings P(1) 36 and 213 as follows: —

1) Vigorous varieties of great ratooning power, giving heavy yields. The limiting factor in Tucuman is the low annual rainfall; in Louisiana this limiting factor disappears.

2) Low cost of cultivation, as they grow very rapidly in spring, Louisiana has the advantage of earlier spring rains than Tucuman, hence early development would be much more marked.

3) Very resistant to the cane borer (*Diatraea saccharalis*). As a point of comparison it may be noted that this was a very serious pest of the Cheribon cane.

4) Much more resistant to frost damage than the Cheribon and the D74, and would probably enable the harvest period to be deferred to a later date, thus eliminating the disastrous effects produced on the stubbles by early cutting and enabling the factories to obtain riper cane for grinding purposes than at present

5) More resistant to root disease (*Marasmius Sacchari*) and mosaic.

6) Greater resistance to the rotting of the stubbles during the winter. The advantage of introducing these seedlings into a country where the winters are moist *e. g.* Louisiana is therefore evident, seeing that the cane from the first year's stubble has up till now been less than the plant cane, and the second year's stubble has given so small a yield as not to be worth cultivating.

7) Much more fibrous than the Cheribon, containing an average of 12.5 % fibre compared with 10.0 or 10.5 % for the latter. This allows for a higher sucrose extraction from the same mill and diminishes the cost for fuel.

M. I. Y.

271 - **Tests of New Methods of Propagating the Sugar-Cane in Cuba.** — CAI VINO, M., in *Revista de Agricultura, Comercio y Trabajo*, Year IV, pp 500-503, figs 2 Havana, 1921

At the Agricultural Station of Cuba the author has tested the method of propagating sugar-cane which was recommended for India, by KULKARNI (1). This consists of cutting the cane into setts of 3 nodes (taking them from a little above the two last nodes), and of removing all the eye-buds, except the one of the middle node. The sett should be planted, so that the eye-

(1) See R. March 1920, No 327 (14)

bud points upwards; in this way a much more vigorous tuft of sugar-canes is obtained than if the eye-bud pointed downwards.

The results were perfectly satisfactory, as is seen from the following comparative data.

*Yield in kg. per Hectare.*

Variety	Sett with one eye-bud	Sett with all its eye-buds
D 74 . . . . .	68 690	63 790
D 99 . . . . .	71 150	61 330
D 108 . . . . .	24 529	23 310
Uba . . . . .	82 800	75 440
Cristalina . . . . .	46 000	36 800

This system can be improved by adopting the practice (devised in Cuba by ABREN and recommended for India by VENKATRAMAN) of letting the setts bud before planting them out, thus giving an opportunity for choosing the most vigorous shoots.

A frame of bamboo is erected at a convenient height above the ground, say 90 cm., and upon it is spread a thin layer of straw which is soaked with dung mixed with a little water. The setts are first dipped in a mixture of dung and water and then piled up roughly on the frame, so that they form heaps, the setts crossing each other in every direction, thus allowing free access to the air. The small heaps are in their turn covered with a layer of straw soaked as before in a mixture of dung, the whole being kept moist by repeated and careful watering.

The increased yield fully compensates for the larger number of workers required. Sometimes, however, lack of labour makes it impossible for the process to be carried out on a large scale, in which case only the cuttings destined for the plantations reserved for propagation can be thus treated.

## LIVE STOCK AND BREEDING.

HYGIENE

### 272 — *Helenium Hoopesii*, a Poisonous Plant harmful to Stock in Utah, U. S. —

MARSH, D. W (Physiologist in Charge of Investigations of Stock Poisoning by Plants) CLAWSON, A. B., (Physiologist), COUCH, J. F. (Pharmacological Chemist), and MARSH H., (Veterinary Inspector, Bureau of Animal Industry), in *United States Department of Agriculture, Bulletin No. 947*, pp. 1-46 tables 13, bibliography of 13 works. Washington, D. C., Oct. 11, 1921.

The "western sneezeweed" (*Helenium [Dugaldia] Hoopesii*) has become very abundant on some of the more elevated and overgrazed stock ranges of the western United States, especially in Utah. It is found in the yellow pine belt, grows also in the aspen and spruce belts and sometimes reaches the arctic alpine zone.

Feeding experiments carried on at the Salina Experiment Station in Utah with sheep and cattle showed that this plant was the cause of the so-called "spewing sickness" of sheep, and cattle also to a certain extent suffered from poisoning.

The symptoms produced by the plant, the pathology and the toxic dosage were all studied in detail. The poisonous principle is an easily decomposed glucoside ("dugaldin") which proves toxic when received orally, intravenously, subcutaneously or by the rectum.

The most marked symptoms are general depression, weak pulse, nausea followed or not by more or less chronic vomiting. Death is not accompanied by convulsions.

No effective medicinal remedy has so far been found. As to the possibility of exterminating the plant, experiments in scythe cutting proved of no avail and experiments are in progress to test the effect produced by restriction of grazing and allowing the range to reseed itself and also as to the possible extirpation of *H. hoopesii* owing to the growth of grasses and weeds.

M. L. Y.

273 - **Use of Stomosines in the Treatment of Infectious Diseases of Live Stock.** — CENTANNI, E., in *L'Italia Agricola*, Year 56, No 12, pp 366-368 Piansance, December 15, 1921.

Stomosines are immunising substances discovered by the author which differ from those hitherto known (serums and vaccines). The latter have a preventive and the former a curative effect; they contain in an innocuous form the principle that destroys the micro-organisms and their poisons.

When the preparation of serums was extended to all infectious diseases, insurmountable difficulties were experienced owing to the different kinds of poisons produced by bacteria and the various ways of neutralising them.

Bacteria are the cause of two distinct sorts of poison, true specific toxins and aspecific endotoxins. The first are the product of a very small number of the least common bacteria consisting almost exclusively of the pathogenetic agents of tetanus and diphtheria; in the case of all the others, the fundamental poison causing the complex of the symptoms is an endotoxin. Since it is impossible to make immunising serums against endotoxins, it may fairly be said that a serotherapeutic has found itself disarmed in the face of most infectious diseases and is unable to intervene with any prospect of success when once the syndrome has declared itself.

In trying to discover what defensive means the organism adopts during the course of the disease, in order to free itself from these poisons and regain health, the author found that the active agent is a ferment or rather a kinase, increasing the activity of the ferments and so constituted that the endotoxins are attacked and burnt, being thus quickly reduced to inoffensive substances.

The author has given the name of "stomosine" to this kinase, which he prepared and isolated by means of chemical processes, taking as his point of departure the protein-bacterial principles arising from the micro-organisms inducing the disease.

The poisons disseminated by the bacteria installed in the organism have two ways of manifesting themselves. Those carried by the blood produce the syndrome of fever and all the local troubles accompanying it (abscesses, sores, ulcers etc.), while the others cause the complex of symptoms resulting in the irritation and inflammation of the tissues surrounding the centre of infection. As is required by this double symptomatology, the action of the stomosines is also twofold, being both general and local.

Shortly after infection, which is followed by violent shivering, a rise of temperature takes place (average  $1^{\circ}$  to  $1.5^{\circ}\text{C}$ ) showing that the combustion of the infected matters has begun. The temperature remains at this level for 8-10 hours and then suddenly falls (the change being accompanied by profuse sweating) to normal, or nearly normal. If the effect is complete, a single injection is enough to produce a cure. Sometimes, however, it is necessary to repeat the operation two or three times to obtain definitive results. In some of the most resistant cases, the disease becomes of a benign character.

The effect upon the local centre is similarly explained: the irritant poisons are destroyed and therefore all the symptoms of inflammation (congestion, exudations, pain), are removed, the surface becomes healthy and cicatrization rapidly takes place.

So far stomosines have been prepared for the chief infectious diseases of cattle (epizootic foot-and-mouth disease, diarrhoea in calves, polyarthritis and septic pneumonia); of pigs (swine fever, septicaemia, paratyphus and measles); of horses (equine adenitis, colt polyarthritis) and of poultry (fowl cholera and avian pest).

Even where the pathogenetic agent is an invisible virus that cannot be cultivated, the effect of the stomosine is satisfactory, probably because also under such a form the actual toxic factor is an intermediate poison of the nature of an endotoxin. This is the case with the virus of epizootic foot-and-mouth disease, swine fever and avian pest; all these diseases and especially swine fever, have proved amenable to stomosine treatment.

Stomosines are agents of an essentially curative character; as soon as they are introduced into the organism, they find themselves in the presence of poisons and bacteria which they attack and render powerless as described above. If, as in the case of preventive infection in a healthy organism, they encounter no pathological element, they remain in the circulatory system, but their power decreases somewhat rapidly in the course of a few days.

Their true use is to effect a cure, and they act even if introduced when the disease is in full development, or actually far advanced, but to obtain a more certain result, they should be employed as soon as the malady first declares itself. If an outbreak of epizootic disease occurs in a stable, not only the first animal attacked should be treated but also all the animals that have been in contact with it, in order to interrupt the incubation of the disease or prevent its occurrence.

Should the disease have made its appearance in the neighbouring stables, a general preventive treatment must at once be begun in all the

threatened stables without waiting for it to assume an epidemic form. In order to prolong the protection, seeing that the immunisation is not of very long duration, the injection ought to be repeated on an average every fortnight, as long as any danger threatens; in this way the owner may be sure that his stock will entirely escape infection or that the disease will assume a benign form in any of the animals attacked.

Stomosine is supplied in two forms: a) liquid for immediate use, b) as a soluble sterilised powder for keeping a long time. The average dose is from 5 to 10 cc. per quintal of weight. The most effective way of using it is in the form of an intravenous injection; this induces the largest number of instantaneous crises and should be adopted for very urgent cases. In ordinary cases since the liquid diffuses very readily, a subcutaneous injection is all that is required. The injection has never produced bad effects, for the substance of which it is composed is an elective kinase without any toxic or anaphylactic action.

F. D.

- 274 - **Protozoan Parasites of Domestic Animals in Transcaucasia.** — JAKIMOFF, W. L., in *Bulletin de la Société de Pathologie exotique*, Vol. XIV, No. 10, p. 652 Paris, December 14, 1921.

In the Chemical and Bacteriological Laboratory of the Malaria-epidemic Mission of the Union of the Russian Zemstvos (which has its Headquarters at Prokhladnoe near Kars), the author and his collaborators found the following protozoan parasites: in cattle, *Piroplasma bigeminum* (peripheral blood); *Sarcocystis blanchardi* (peripheral blood and blood of heart); *Trypanosoma theileri*; in camels from the Government of Sakaspinsk, the author's colleagues, the veterinary surgeon, JILINI and Dr. SOULINA SAMAILO found *Trypanosoma Ninae Kohl-Jakimoff* which the author had already met with in 1913, in the camels of Turkestan (1).

No microfilariæ, or endoglobular parasites were discovered either in the horses or dogs.

F. D.

- 275 - **Researches on the Mite-Destroying Power of some Substances used against Parasitic Mange in Horses.** HENRY, A., in *Recueil de Médecine vétérinaire*, Vol. XCVII, No. 18, pp. 355-370 Paris, September 1921.

In order to test the various substances used as remedies against parasitic horse-mange the author made use of the methods most commonly employed which consists in placing the parasite (sarcoptes or psoroptes) in contact with the substance and observing under the microscope how soon the insect dies, or rather how long it can live, its resistance being proportionate to the activity of the acaricide. As a counter-test (to determine if death is real or only apparent and a reflex protective device,

(1) In Russia in Europe (Government of Astrakhan), the trypanosomes of the camel were found in 1912 and in Russian Turkestan and the Ural in 1913 and 1914 respectively. W. L. JAKIMOFF and Mlle W. J. WASSILIEVSKY (*Bulletin de la Société de Pathologie exotique*, Vol. XIV, No. 10, pp. 637-640) have established the identity of the Turkestan and Ural trypanosomes. The researches made by MICHIL at JAKIMOFF'S request, have proved that these trypanosomes differ from those of "surta" (*Trypanosoma evansi*), and of "debab" (*Trypanosoma sudanensis*).

as the author express it), the dead or apparently dead mites are put into peanut oil at 30-32° C, an artificial medium considered the most suitable by the author, seeing that the parasites are able to live in it for several days without any inhibition of some of their functions. The author defines the unit of acaricide power as the capacity for killing psoric mites in 5 minutes at the temperature of 30-32° C. Thus, beech creosote which kills the mites in 2 minutes, has an acaricide power of 2.5; pea-nut oil dissolving sulphurous acid in the proportion of 1% (by weight), has an acaricide power equal to unity, because it kills the psoric mites in 5 minutes at 30-32° C; and a 2% aqueous emulsion of cresyl destroying the mites in 10 minutes has an acaricide power of 0.50.

The other substances tested gave the results set out in the following Table. The author draws from them the following conclusions which are of practical importance

1) Sulphurous acid dissolved in oil proves to be the most effective acaricide (it is not necessary to increase the saturation beyond 2.5%; as this does not make the activity greater)

2) A 1 or 2% warm or tepid, aqueous emulsion of cresyl is the most energetic anti-acarian disinfectant. F D

276 - **A New Disease of Oxen: Contagious Acute Encephalitis.** — DONALD N. A. and BOSSHUIS, R., in *Comptes rendus de l'Académie des Sciences*, Vol. 174, No. 1, pp. 250-252 Paris, January 23, 1922.

The authors report a contagious disease that during the autumn of 1921 carried off 9 of the oxen in a herd belonging to a farm near Algiers. The symptoms of the disease were signs of madness and abundant salivation; there were no actual lesions.

Experimental research showed, that it was a contagious complaint transmissible in series to the ox, rabbit and guinea-pig. It is due to a new neurotropic virus which should probably be placed in the same category as the human diseases, encephalitis lethargica and acute anterior poliomyelitis. F D

277 - **Vaccination of Cattle against Rinderpest.** - NICOLAS, E. and RIVARD, P., in *Comptes rendus de l'Académie des Sciences*, Vol. 173, No. 25, pp. 1428-1429 Paris, December 10, 1921.

The countries where rinderpest has become endemic (Eastern Europe, Asia and Africa) cattle are inoculated against this fatal malady according to KOLLE and TURNER's method which has now become universal. This method consists of infecting, at the same time and into two different places, a small quantity of virulent blood, 0.2 cc., to 1 c.c., or more (taken from an animal suffering from rinderpest, and at the height of the fever-period), and also anti-rinderpest serum in proportions varying according to the activity of the serum and to the size of the animal to be vaccinated. The amount must however be sufficient to insure that this double simultaneous infection, which is a real sero-infection, shall be followed by a "good reaction", that is to say one that after a short incubation period, lasting usually 3 to 5 days, results only in a rise of temperature that may regis-

ter as much as 41° C and is quite compatible with a satisfactory condition of health, for no lesions of the mucous membranes are developed although a slight degree of lachrymosis is frequently present. After, such a reaction the animals are as effectively and durably immunised as if they had recovered from the disease.

When well carried out this method gives excellent results, fatal effects being most rare ; it has, however, one serious drawback, that of producing in the inoculated animal a reaction that not only has the appearance of rinderpest, but is actually due to an attenuated form of the disease. Hence the vaccinated individual becomes a source of infection to healthy animals capable of contracting the malady, so that if care is not taken this method increases the sources of virus and becomes a means of spreading and perpetuating rinderpest.

This evil can be remedied by vaccinating in zones, but it is possible greatly to lessen, and perhaps, cause it to disappear, by increasing the amount of serum injected, so as to effect a "silent" vaccination. This seems to be proved by the results of experiments observed by the authors during the course of the Mission to Belgium with which they were entrusted during the epidemic of 1920.

They certainly found on various occasions, that by using the right doses of serum of which the effect has been ascertained by comparison with that of a known virus, it is possible to avoid producing any external symptoms that can be detected by the examination of the patients. Vaccination was however attained, as was shown by the fact that the test experiment with pure virus had no effect, any more than the subsequent injections of large quantities of virulent blood which were made with a view to hyper-immunisation.

This being the case it is probable that active vaccination, "silent" in so far that it produces no apparent reaction on new subjects, cannot create a dangerous centre of infection in the zone where it is carried out. This form of vaccination will therefore be the one most usually adopted.

F. D.

278 - **Summary of Experiments on Foot-and-Mouth Disease (1) in France.** - ROUX, E., VALLEE, H., CARRÉ, H. and NOCARD (the late). in *Comptes rendus de l'Académie des Sciences*, Vol 173, No 23, pp 1141-1145 Paris, December 5, 1921

At the request of the French Government, the authors have been making researches on foot-and-mouth disease. Their work, which was begun in 1901, was only interrupted during the period of the War.

In the paper analysed they give a summary of the results of their investigations.

Like LÖFFLER and FROSCH they used young pigs (as being susceptible animals) for preserving the aphthous virus by means of successive transmissions. Between each transmission, the virus is kept in a refrigerator

(1) For other studies on epizootic foot-and-mouth disease, see R. 1911, Nos. 890, 2197, 2783 ; R. 1917, No. 954 ; R. 1916, Nos. 601 and 768 ; R. 1919, No 923 ; R. 1920, Nos. 335, and 882 ; R. 1921, Nos 309, 731, 735, 829 and 1019. (Ed.)

at temperatures below 0° C. This method has the defect of only providing limited supplies of virus.

The lymph from the vesicles and the serous liquid retain their virulence intact for no more than 3 weeks in the refrigerator; further, the lymph is bacteriologically impure.

As a source of virus, blood taken from infected heifers during the time their temperature is rising is far preferable. The authors use no anti-coagulants in their technique, substituting for them mechanical defibrination. The preservation of the virulence of the defibrinated blood is practically insured for 2 to 3 months if the blood is kept at temperatures varying from -10° C to +20° C.

The accidental introduction of extraneous matter seems to have no effect upon the keeping-qualities of the virus; it is however injured by dilution.

Pounded fragments of the desquamated epithelium and lymph from the vesicles are infectious after dilution to 1/20 000. The issues from the pericardium retain their virulence to 1/1000, whereas blood serum ceases its regular pathogenetic action, if inoculated in amounts of less than 0.2 cc.

It is a mistake as has been found by the authors, to regard aphthic virus as easily destroyed. Desiccation for instance does not exercise the deleterious effect that was supposed.

With the exception of intradermic and intramuscular inoculation, which (especially when substances containing foreign matter difficult of absorption are employed) are very severe methods of introducing the virus, and also of the frequently dangerous process of intra-venous inoculation, all the experimental methods of aphthic infection are incomparably less severe than the forms of natural contagion.

Already over 30 years ago, NOSOTTI (*Clinica veterinaria*, 1885, p. 101) considered the question of immunisation by the sub-cutaneous inoculation of virulent lymph.

The author studied the question from the beginning of their researches, and the results of their investigations as to the most favourable conditions for the re-absorption of the aphthic virus led them to use for subcutaneous infection clear, virulent, blood-serum that had been fixed by remaining 1 month in the refrigerator. The dose to be injected beneath the skin must not be less than 1 cc. Larger amounts are sometimes troublesome. If carried out properly, experimentally induced foot-and-mouth disease only causes the development of the malady in the mouth-cavity.

Artificial anti-aphthic immunity is not lasting, and disappears in less than 6 months, even in hyper-vaccinated animals. This gives little hope that the problem of anti-aphthic immunisation will ever be completely solved.

F. D.

279 - **Intestinal Coccidiosis of the Pig.**—CAUCHEMEZ, L., in *Bulletin de la Société de Pathologie exotique*, Vol. XIV, No. 10, pp. 645-648, fig. 1. Paris, December 14, 1921.

From researches at the Laboratory of Parasitology of the Faculty of Medicine in Paris and at the Laboratory of the Vaugirard Abattoir,

the author has discovered that intestinal coccidiosis is a disease of very frequent occurrence in swine, 26 % of the animals examined being found to be affected. The disease assumes a mild form in adult pigs causing no disturbances or lesions. Its presence may, however, serve to explain serious intestinal affections in quite young pigs. If the latter are attacked by a mild form of coccidiosis, they soon recover and have been rendered immune to the malady. There is but little literature on the subject, and in the absence of all experiments of reciprocal immunity, it is impossible to say whether the coccidiosis of cattle and swine is identical. The author proposes the provisional name of *Eimeria brumpti* for the pathogenic agent in swine coccidiosis. It differs from the 3 species of parasite attacking man and identified by C. DOBELL as belonging to the genus *Eimeria* and there is therefore no reason to suppose that swine coccidiosis can be transmitted to human beings.

I. — EFFECT OF LIMITED FOOD ON GROWTH OF BEEF ANIMALS. — The objects of these experiments were to determine: 1) if an immature animal can use its stored fat to protect growth when sparsely nourished and to what extent the body fat may be relied upon to insure the continuation of growth; 2) the changes that occur in the composition of the bodies of immature animals when kept for a considerable time on a so-called maintenance ration, and also the changes that take place when such animals are kept on a ration above maintenance, but insufficient to supply the maximum growth of which the animal is capable. This work is of practical importance for it is a common habit among many farmers to bring young cattle through the winter with practically no gain in weight, so that these animals make a very marked skeletal growth and become very thin.

In October 1907, a number of closely related steer calves that had been dropped early in the preceding spring were taken and put on a liberal feed. Seven thrifty yearling animals were later selected from among them, and 6 were given the experiment rations, 3 for 6 months and 3 for 12 months, they were afterwards slaughtered and analysed. The 7th was slaughtered and analysed at the outset of the experiment and used as a check animal, the composition of its body being taken as representative of that of the other animals at the beginning of the experiment. Of the remaining steers (Nos. 593 and 599), the fattest and thriftiest, were fed so as to gain  $\frac{1}{2}$  lb. per head per day; Nos. 597 and 595 received a ration producing no

change in their weight, and the thinnest pair (Nos. 591 and 592), were fed to lose  $\frac{1}{2}$  lb. per head per day.

At the beginning of the experiment (February 25, 1908) the calves were from 9 to 12 months old. The same ration was supplied to all the animals, the only variation being in quantity. The grain (maize chop 8 parts, linseed meal 1 part) was fed twice daily in equal amounts, the hay was fed at night only and was  $\frac{4}{10}$  as much as the daily grain ration. One animal of each group (Nos. 591, 597 and 593), was slaughtered on September 1. In November a digestion trial was made with the remaining animals. The results are given in Table I.

TABLE 1. — *Coefficients of Digestibility for Steers on different Planes of Nutrition.*

	Super Maintenance	Maintenance	Sub Maintenance
Protein . . . . .	69.614	66.644	61.574
Fat . . . . .	83.781	84.042	81.043
Crude fibres . . . . .	43.296	29.117	30.048
N-free extract . . . . .	85.478	82.485	79.699
Total nutrients . . . . .	77.521	73.374	70.559

The figures show that the condition of the animal has a great influence upon its digestive capacity; a very meagre ration diminishes the coefficient of digestibility.

When a fat yearling steer is kept at body weight maintenance for one year, his maintenance cost in nutrients per thousand pounds of live weight is only slightly less during the first 6 monthly period than the second. During the first period the impetus to grow causes the addition of flesh and bone. Fat must be consumed to maintain constant weight, thus supplementing the ration. During the second period, the impetus to grow is less, there is more active tissue to maintain and less available fat; hence the increased demand for food to maintain body weight.

During the first 188 days of the experiment, Steer No. 595 consumed in nutrients 8.06 lb. per day per thousand pounds, during the second period 8.20 lb.

As regards the 2 steers fed the submaintenance ration, during the first 188 days, one pound loss in weight effected a saving of 1.9 lb. of nutrients for No. 591 and of 2.8 lbs. for No. 592. During the second period (139 days), the loss of 1 lb. in weight effected a saving of 4.5 lb. of organic nutrients. For the total period of 329 days, 3.7 lb. of organic nutrients were saved by each pound of weight lost.

In the case of the 2 steers given the supermaintenance ration, during the first 188 days, per 1 lb. gain in live-weight required (in addition to the maintenance ratio), an extra consumption of 2.6 lb of organic nutrients by steer No. 593, and of 3.6 pounds by steer No. 599. For the

second period, the cost was 2.0 lb. and the average for the 362 days 3.0 lb. In the growing animal the cost of gain above the calculated maintenance ration appears to decrease during the second year of the animal's life.

Every month, 32 measurements were taken of each animal, in order to follow the changes in the skeleton. In this way the exact contour at the heart, paunch and flank girths was obtained. A chain of aluminium links, each one adjustable by means of a set screw, was used for measuring. It was found that the growth in height and length was not affected by the insufficiency of the ration. Later, the sub-maintenance animals stopped growing.

As the sub-maintenance animals lose weight, there is loss in amount of blood, but when the loss of weight is very great, the loss of blood is not proportionate to the loss of weight. With the maintenance and super-maintenance animals the ratio of hide to animal increased; with the sub-maintenance steers the hide apparently lost weight as did also the heart, liver, spleen and pancreas.

The authors give in their tables accurate data showing: the food consumed during each 10 days' period, the chemical composition of the food; the live-weight for each ten-days period; the body measurements (taken every month); the weight and composition of each organ and of the different parts of the body when the animal was slaughtered.

A summary of some of the most important data for the solution of the problems the authors had in mind are given in Table II.

TABLE II. — *Changes in the Chemical Composition of Steers over One Year of Age on Different Planes of Nutrition.*

No. of animal	Average daily change in live-weight	Duration of feeding period	Whole animal			Adipose texture		Lean Flesh		Skeleton		
			Moisture	Fat	Protein	Moisture	Fat	Moisture	Fat	Moisture	Fat	Ash
	gm.	Days	kg.	kg.	kg.	kg.	kg.	kg.	kg.	kg.	kg.	kg.
592 . . . . .	- 270	327	- 26.4	- 44.3	- 10.9	- 5.1	- 27.9	- 27.3	- 8.1	- 10.3	- 4.9	+ 0.55
591 . . . . .	- 200	188	- 16.4	- 25.1	- 3.9	- 1.0	- 19.2	- 12.8	- 5.6	- 1.1	- 1.6	+ 0.21
595 . . . . .	- 9	362	+ 10.3	- 20.5	+ 1.8	- 0.5	- 17.6	+ 7.5	- 3.5	+ 1.6	+ 1.6	+ 2.04
597 . . . . .	+ 32	188	- 1.6	- 1.3	+ 0.1	- 2.7	- 2.1	- 5.6	- 2.2	+ 0.2	+ 2.9	+ 0.39
593 . . . . .	+ 240	188	+ 13.5	+ 10.5	+ 3.1	+ 1.9	+ 6.8	+ 6.9	+ 0.5	+ 1.4	+ 2.2	+ 1.53

The authors draw from these data the following conclusion: when large amounts of fat are used by the animal as a source of energy to supplement a limited food supply, some of this fat is replaced by water.

The skeleton continues growing even under feed restrictions; its growth consists in an increase in protein and fat, as well as in mineral constituents.

When young beef animals in good condition are put on a ration insufficient to provide for normal growth, there is a very persistent tendency to grow in spite of feed restrictions. Much of the surplus fat will be used for

energy, and growth of both lean flesh and skeleton will continue. Later with continued food restrictions the animals will draw on both the residual fat supply of the soft parts and also on the protein of these parts to maintain existence and promote a normal growth of the skeleton which even includes the storing of fat in the latter. As the fat supply of the soft parts becomes more seriously depleted and much of the protein of the soft parts is used to preserve existence, the animal is able to make use of the fat supply of the skeleton until it is almost entirely exhausted.

II. — COMPOSITION OF THE BEEF ANIMAL AND ENERGY COST OF FATTENING. — The objects of this investigation are to determine 1) the chemical composition of the gain made by steers in the process of being fattened; 2) the changes that take place in the form of the animal when it passes from the maintenance ration to the fattening ration, 3) the moment when the steer is just fat enough for all rational demands of the consumer, and how far this condition differs from that required by the market.

The principle results bearing on the first question have already been given by MOULTON in a preceding paper (1), in the work analysed, in addition to the data concerning the 3 steers (Nos. 18, 124, and 48), (which are chiefly used for the solution of the first question) are included those referring to 4 other steers of the maintenance group. Tables are given showing the amount of nutrients consumed by steers Nos 121 and 48 and two others during the full period which succeeded the maintenance period; the weight of the carcasses and offal of each of the 7 animals the chemical composition of the organs and of the different cuts of steers No 18, 121, 48 and of 1 of 4 other steers

In order to study the changes in the form of the animals, a number of measurements were taken at short intervals, the exact contour of the animal being taken at heart, paunch and flank either by a chain of aluminium links adjustable at each joint by means of set-screws or else by a hinged wheel with adjustable blunt prongs. The latter apparatus was devised by F. G. KING and J. M. EVVARD.

From the total results obtained it may be gathered that when steer No 121 passed from the thin condition of steer No. 18 to the average fat condition at which it was slaughtered, the lean flesh of the carcass increased 54 % and the soluble fat 284 %, while the whole carcass increased 76 %. The production of this amount of fat was in no sense waste, for it would all have been eaten by persons appreciating good meat. On the other hand the fat, lean flesh and carcass gains of No. 48 (the highly fattened animal), over the steer brought to the average fat condition were respectively 122 %, 20 % and 47 %. The fat in the highly fattened animal was too plentiful for the tastes of normal persons and therefore the energy employed in producing it was wasted.

III. — COMPOSITION OF CATTLE AT BIRTH (2). — For these researches

(1) See R. April 1918, No 411 (Ed)

(2) The *Research Bulletin* No 35 of the University of Missouri Agricultural Station deals with the Birth Weight of Calves. This work has been summarised from another source in R. July 1919, No 944 (Ed)

7 aborted fetus or still-born Jersey calves and 13 Hereford calves slaughtered soon after birth were used.

The mothers were fed during gestation a grain ration of 6 parts of maize + 3 parts of bran + 1 part of linseed with roughage consisting of 3 parts of lucerne hay and 2 parts oat-straw. The cows and their calves were divided into 3 groups according to their rations of concentrates viz., high (which caused the cows to become fat during gestation); average (which kept them in good condition without fattening); low (this kept the cows in the condition of cattle on a southwest range under arid conditions. All the animals received as much roughage as they could eat

The authors obtained the following data which they arranged in Tables: — weight of blood; of the hair and hide; of the meat (fat and lean); of the skeleton; of the most important internal organs; of the excreta and of the kidney fat: the chemical composition of the blood, liver, nervous system, organs taken together, the hair and hide, skeleton, meat, marrow, kidney fat, contents of intestine, entire animal. The averages of the analyses of the whole animal, the flesh (fat and lean), and of the skeleton are summarised in Table III.

TABLE III. — *Percentage Composition of New-born Hereford Calves and Still-born Jersey Calves.*

Race and feeding of the pregnant cows	Entire Calf					Meat				Skeleton				
	Water	Fat	Nitrogen	Ash	Phosphorus	Water	Fat	Nitrogen	Ash	Water	Fat	Nitrogen	Ash	Phosphorus
<i>Hereford:</i>														
Abundant . . . . .	72.4	4.15	3.00	1.15	0.805	76.3	4.41	2.79	0.984	64.3	3.97	2.88	12.81	2.60
Average . . . . .	72.5	3.57	2.97	1.51	0.809	76.5	4.07	2.77	0.988	65.0	3.36	2.85	13.18	2.51
Insufficient . . . .	73.0	3.24	2.81	1.91	0.915	78.2	3.62	2.57	0.993	65.4	3.03	2.78	13.57	2.67
General average . .	72.8	3.65	2.93	1.52	0.841	77.0	4.01	2.71	0.989	64.9	3.45	2.83	13.19	2.59
<i>Jersey . . . . .</i>	73.4	3.82	2.88	1.15	0.681	77.4	3.12	3.19	0.974	63.0	2.18	3.21	13.85	2.43

The weight of the stomachs and intestines, and consequently of the internal organs as a whole are a higher percentage of the live-weight of the animal in Jersey calves than in Hereford calves. The weight of the hair and hide and possibly of the skeleton of the Hereford calves is higher in proportion to the live-weight than in the case of the Jersey calves. There is no apparent difference in chemical composition due to breed.

As regards the effect of the feeding of the cow during the gestation period (Herefords), it was found that the live weight of calves at birth from the high and medium planes of nutrition were practically the same, whereas that of calves whose dams were insufficiently fed was appreciably lower.

As regards the separated parts of the animal, the proportion of flesh

decreases and the proportion of skeleton and internal organs increases as we pass from the high plane of nutrition to the low plane.

Taking the average composition of the calves the proportion of fat and nitrogen decreases and that of moisture, ash and phosphorus increases as we pass from the high to the low plane of nutrition. Most of the fat of the new-born calf is found within the internal organs; the flesh and skeleton also contain fat but in small proportions. The sum of the percentages of moisture and fat, and consequently the percentage of moisture-free substance tends to a constant value, regardless of the plane of feeding of the dam.

IV. — THE NORMAL GROWTH OF DAIRY CATTLE. — In a preceding treatise (1) the factors influencing the rate of growth and the size of dairy heifers was studied. In the present Research Bulletin a more detailed study is made for determining the processes of normal growth and how it is attained.

The authors in order to arrive at a decision plotted the growth curve from birth to maturity (as represented by weight and height at withers), for cows of the Jersey, Holstein, Ayrshire and the dairy type of Shorthorn. They also collected data showing the average height at withers and weight of mature Jersey Holstein and Ayrshire cows.

Curves of this character are useful in research work as a basis of comparison for the growth of experimental animals. The figures of normal growth may be of considerable assistance to breeders of dairy cattle, giving them a means of determining whether their methods of feeding growing animals are such as to allow growth to continue at a normal rate, and to judge if an individual animal is of normal size for its age.

Table IV and V give some of the most important data.

TABLE IV. — *Average Weight of Jersey, Holstein and Ayrshire Cows from 1st to 5th Calving.*

	Holsteins		Jerseys		Ayrshires	
	Age	Weight	Age	Weight	Age	Weight
	Months	lb.	Months	lb.	Months	lb.
After 1st calving . . . . .	30	965	29	764	28	868
Six months after first calving . . . . .	36	962	35	779	34	840
After second calving. . . . .	43	1040	42	827	37	874
Six months after second calving . . . . .	49	1071	48	854	43	892
After third calving . . . . .	57	1143	55	872	55	960
Six months after third calving . . . . .	63	1136	—	—	61	952

Ayrshires . . . . .	123.6	997

V. — STUDIES IN ANIMAL NUTRITION: CHANGES IN FORM AND WEIGHT ON DIFFERENT PLANES OF NUTRITION. — About 60 Hereford-Shorthorn beef steers were fed from a few weeks of age on milk, lucerne hay, and a grain ration of maize chop + whole oats + linseed meal in the ratio of 6:3:1. The ratio of grain to hay was: 2:1. The animals were weaned at ages varying from 2 to 7 months.

Three planes of nutrition were used 1) Full feed from birth; 2) Feed to produce maximum growth without appreciable fattening; 3) Feed for scanty and retarded growth. The length of the feeding period varied from a few weeks to 4 years.

The average daily increase in live-weight for the 4 years was 1.30 lb. for Group I 0.80 lb. for Group II and 0.65 lb. for Group III. The cost per lb. of gain was 12.24 lb. of dry matter for Group I, 11.91 lb. for Group II, and 11.03 lb. for Group III.

The growth of the Group I animals, as shown by height, width and length measurements, is considered as representing normal growth for this type of cattle. Growth is more rapid at the earlier ages and becomes much slower when the animal is older.

At 4 years the normal beef steer should be 140 to 150 cm. in height at the withers and hips, about 65 cm. wide at the hips and 187 cm. long from shoulder to rear of ischium. The heart girth should be about 250 cm.

The scantily fed cattle grew less rapidly in all respects. But when 4 years old they were of the same height as the full fed group. The age at weaning or at which they were put on poorer rations seems to have had no effect upon the ultimate height. Even a long maintenance period during the first year made no difference to their height.

The poorer rations brought about a material decrease in length, width and circumference of body, and in body weight. The animal kept at body weight maintenance for the greater part of a year failed to catch up in these respects even after 3 years.

The different rations fed seem to have no effect upon the breaking strength of the bones other than such as was due to increased weight. For all 3 groups the breaking strength was a function of the live weight. The formula is approximately  $L = 16.5 W^{.68}$ , where  $L$  is the breaking load and  $W$  is the live-weight.

For very fat Group I cattle this gives results much higher than the observed breaking load.

F. D.

281 - **Hay Made from Liberally Fertilised Young Grass, a Farm-Grown Concentrated Food.** — I. NEUBAUER, Die Gewinnung von jungem Grass nach starker Stickstoffdüngung, ein Mittel zur Erzeugung von Kraftfutter in der eigenen Wirtschaft, in *Biedermann's Zentralblatt*, Year 4, Part 7, pp. 272-275. Leipzig, July 1921. — II. HÜTTINGER, Welche Nutzwendungen muss der practische Tierzüchter aus den Kriegserfahrungen für die Züchtung seiner Nutztiere ziehen? in *Deutsche Landwirtschaftliche Presse*, Year 49, No. 1, pp. 1-2. Berlin, January 4, 1922.

I and II. — NEUBAUER and HÜTTINGER point out the economic importance of a farm being self-supporting, especially as regard stock-feeds including concentrates.

Hay made from young grass possesses the two qualities necessary for concentrated feeds, a low fibre content and a high percentage of protein (20 to 23 per cent of dry matter as against the 12 % found in ordinary hay). As a concentrated food, young grass (the dry matter content being equal) has almost as high a value as brewers' grains, and it is also a very wholesome diet.

NEUBAUER carried out his experiments in a good meadow on the lower Rhine. One part of the ground was mown 3 times in the year, and another every 2-4 weeks (at longer intervals in periods of drought). A portion of the latter plot was left unfertilised, while the other was liberally dressed with sulphate of ammonia each time the grass was cut, from 12 to 16 quintals of the fertiliser being applied per annum. The results obtained are given in the following Table.

*Effect of a Nitrogenous Fertiliser on the Production of a Meadow.*

Years	3 cuttings per annum without fertiliser		From 6 to 8 cuttings per annum			
			Unfertilised		Fertilised	
	Dry matter per hectare kg.	Protein per hectare kg.	Dry matter per hectare kg.	Protein per hectare kg.	Dry matter per hectare kg.	Protein per hectare kg.
1916 . . . . .	10 364	1 483	6 575	1 325	10 358	2 265
1917 . . . . .	6 277	884	4 603	862	7 934	1 706
1918 . . . . .	6 807	947	4 299	912	8 169	1 954
1919 . . . . .	—	—	4 108	685	7 465	1 375

The fertiliser increase the grass-crop by about  $\frac{1}{3}$ ; the dry matter content, whether expressed as weight or as starch value, was increased in about the proportion of 100 to 180; the protein content was nearly doubled.

F. D.

282 - Connection between Degree of Milling and the Composition and Food Value of Bran. — HONCAMP, F., and NOLTE O., in *Landwirtschaftliche Versuchs-Stationen*, Vol. XCVI, pp. 121-142. Berlin. Summarised in *Biedermann's Zentralblatt*, Year L, Part 7, pp. 266-268. Leipzig, 1921.

Table I gives the results of the analyses of rye and wheat brans obtained with various degrees of milling. The authors fed these brans to lambs and determined the coefficient of digestibility for each constituent; the percentages of digestible nutrient substances given in Table II were thus obtained.

TABLE I. — *Percentage Composition of Brans  
Obtained by different Degrees of Milling.*

		Organic matter	Crude Protein	Pure Protein	h-free extracts	Crude fats	Crude fibre	Ash
<i>Wheat bran</i>								
	Milling 75 %	94.97	17.02	15.56	65.62	4.61	7.72	5.03
	" 83 "	93.89	17.32	15.33	62.18	5.08	9.31	6.11
	" 94 "	95.28	15.28	13.21	62.62	4.28	13.10	4.72
<i>Rye bran</i>								
	Milling 65 %	96.41	15.51	13.35	74.14	3.30	3.46	3.59
	" 84 "	96.07	16.37	14.80	70.50	3.87	4.33	4.93
	" 94 "	92.52	19.04	17.08	57.87	4.99	10.62	7.48

TABLE II. — *Percentage of Digestible Nutrient Substances  
Obtained by different Degrees of Milling.*

		Crude protein	Pure protein	N-free extracts	Crude fats	Crude fibre	Starch Value
<i>Wheat bran</i>							
	Milling 75 %	14.36	12.9	52.82	4.05	2.13	51.2
	" 83 "	14.19	12.2	46.95	4.29	3.71	48.1
	" 94 "	11.02	8.9	30.12	3.45	4.89	40.0
<i>Rye bran</i>							
	Milling 65 %	12.08	9.9	64.28	2.53	2.06	57.4
	" 84 "	12.77	10.2	60.42	3.01	1.78	54.9
	" 94 "	14.85	12.8	26.74	3.97	5.89	33.4

These data prove that the degree of milling is a good measure of the food value of a bran, the finer the milling, the lower is the value of the bran.

283 - Colour Inheritance in Mammals and Domestic Birds (1). — PORCHEFEL, A., in *Revue vétérinaire*, Vol. LXXII, No. 9, pp. 541-548; No. 11, pp. 680-690. Toulouse, Sept. and Nov. 1921.

The author shows in the first place that the germs of the elements constituting the various colours of the plumage, fur and coats of the dif-

(1) See R. Jan. 1920, No. 81; R. Aug. 1921, No. 832. (Ed.)

ferent breeds which have been evolved are to be found in the plumage, fur and coats of the primitive types from which these breeds are derived. He then investigated colour inheritance and gives a summary of several studies on this subject and finally describes his own experiments with rabbits.

MAMMALS. — As regards *cattle*, Marcel VACHER (1) reached the following conclusions :

1) Red bull and cow:  $\frac{5}{8}$  of the progeny are red and less than 1 % are white.

2) If one of the parents is white and the other red, 90 % of the progeny are roan, 4 % red and 6 % white

3) Two white parents nearly always produce white offspring

4) One white parent and the other piebald-red or roan have red, white and roan calves in variable proportions.

5) Two roan parents produce offspring of all the various colours and shades of coat met with in the Durham breed, viz. red, roan and even white

6) The first calf of a Charolais bull and a red Durham cow was a heifer with light-red coat, all the cows from this first cross were served by a white Charolais bull, and only 6 % of the progeny were white

As regards *horses*, many data have been collected

According to WILCKENS, 5743 matings of animals registered in the English Studbook (3016 of the animals being pure-bred, 1865 English half-bloods, and 861 pure-bred or half blood Arabs) gave the following results :

English thorough-breds a) parents of the same colour transmit their coat colour in the proportion of 85.6 % ,

b) when the parents are of different colours 43.7 % of the offspring inherit the coat colour of the sire, 50.8 % that of the dam, 5.5 % differ in colour from both sire and dam

When the parents are of the same colour, a chestnut coat is the one most frequently transmitted 97.6 p 1000

If the parents are of different colours, bay appears in 50 to 60 % of the foals.

In similar cases, black is much more rarely transmitted. 10 % only of the foals being black.

The same proportions occur in half-blood English horses

When pure-blood and half-blood Anglo-Arabs are of the same colour, they transmit their coats in 83.7 % of the cases

Should the parents be of different colours, 31.3 % of the foals inherit the sire's coat, 50.6 % the dam's coat, and 12.1 % do not inherit the coat of either sire or dam.

White or light-grey parents transmit their coat colour in 90 % of the cases.

(1) M. VACHER, Transmission de la couleur chez les animaux de la ferme *Bulletin de la Société Nationale d'Agriculture de France*, 1905 (Author's note)

If they are of different colours, white is dominant in 73 % of the cases.

Bay is transmitted in 55.1 % of the cases, and black in 19 %.

CABRIFORCE (1) by examining the pedigrees of 197 horses at the annexe of the Saint-Julien remount Station obtained the following data

The offspring of a stallion and brood-mare of similar coat colour usually inherit the coat of the parents (81%). In such cases, chestnut is the colour that is most likely to be transmitted, occurring 95 times out of 100 whereas bay is only inherited 77 times out of 100. When a stallion and mare of different coat colours are mated, the offspring nearly always (90 times out of 100), inherit the colour of one or other parent.

The dam seems to exercise a preponderant influence upon the coat-colour of the offspring ; 58.5 times out of 100 the foals are the colour of the mare and only 41.5 times in 100 do they inherit the coat-colour of the sire

A chestnut coat which is so surely transmitted, when both parents are chestnuts, also occurs frequently when one of the parents is a chestnut, or even when both are of another colour ; 39 matings of a bay stallion with bay mares gave 9 chestnut foals, of which 3 were dark chestnut with mane, tail and legs darker than the coat. Grey coats are also transmitted in rather high proportions :

a) 22 matings of chestnut stallions with grey mares resulted in . 50 % grey foals ; 36.3 % chestnuts , 9 % bays ; 4.5 % blacks.

b) 6 matings of a grey sire and chestnut dam resulted in . 3 grey offspring and 3 chestnuts

c) From 10 matings of a grey sire and grey dam were obtained : 40 % bay foals ; 50 % grey , 10 % chestnut

d) 11 matings of a grey sire and grey dam resulted in . 54.5 % grey foals , 36.3 % bays , 9.0 % chestnuts

e) From 2 matings of grey parents 1 grey and 1 chestnut foal were obtained

A black coat is transmitted with the greatest difficulty . 11 animals with black coats (6 stallions, 5 mares), on being mated with animals of a different colour, transmitted their coat once only.

a) A chestnut sire mated with a black mare produced one brown-bay foal ;

b) Four other matings of bay sire with a black mare gave 3 bay foals and one chestnut ;

c) Four matings of black sire with bay dam produced 1 black foal, 1 chestnut and 2 bay, of which 1 was a dark brown-bay ;

d) With a black sire and chestnut dam a brown-bay was obtained ;

e) With a black stallion and a grey mare, a dark-grey foal was obtained.

CABRIFORCE's statements as regards the influence of the dam's

1) CABRIFORCE, Observations hippiques sur le contingent de 1899 Influence des reproducteurs sur la robe des produits, in *Recueil de memoires et observations sur l'hygiene et la medecine veterinaire militaire*. (Author's note)

coat-colour upon that of her offspring, the difficulty of transmitting a black coat and the facility with which chestnut and grey coats are inherited entirely corroborate the statements of WILCKENS.

DUPAS, quoted by FLORIOT (1), has also collected some data respecting the 300 horses at the Fontenay-le-Comte Remount Station which may be summarised as follows:

1) Inheritance frequency of coat-colour: *a*) bay, is transmitted 208 times out of 310 (66 %); *b*) chestnut is transmitted 87 times out of 181 (48 %), roan, is transmitted 5 times out of 11 (45 %), grey, 5 times out of 30 (17 %), black, 3 times out of 25 (12 %).

2) Sex influence Stallions transmit their coat colour more frequently than mares, the transmission percentage being 48 for the former and 39 for the latter.

8) Transmission of coat-colour of parents when sire and dam are of the same colour 85 % of the offspring inherit this colour a chestnut coat is more easily transmitted (91 out of 100 times) than a bay (83 out of 100 times).

In *summa*, a white coat is most easily transmitted. As regards rabbits Gustave LOIZEL (2) has drawn the following conclusions from the results of his experiments.

From a black buck-rabbit mated with a Russian doe, 9 black young were obtained.

A grey buck-rabbit mated with a Russian doe produced a litter of 8 grey and 3 black. These young rabbits, when mated together, produced 74 offspring, of which 58 had the characters of the grey rabbit and 16 those of the Russian rabbit.

As was to be expected in such close in-breeding, the young Russian rabbits of the last litters showed a tendency to lose the coloured spots characterising the breed, and for the same reason, large white patches appeared on the head and shoulders of the young grey rabbits of the same litters.

The mating of a white Angora buck-rabbit with a grey doe-rabbit resulted in 3 litters of 26 grey young with black eyes, which either inherited from the male brushes of long hair underneath their paws or else were entirely grey-Angoras.

An ordinary dark-grey buck-rabbit with white on the forehead, tip of the nose, the neck and tips of the fore-paws, when mated with a white Angora doe-rabbit produced in 3 litters, 9 young, all resembling the breed of the buck, and with white markings distributed as follows; one dark-grey rabbit had a white star on its forehead, another was dark-grey with a white star on its forehead and white tips to its fore-feet, a third had the

(1) FLORIOT, L'hérédité chez le cheval, *Revue vétérinaire militaire*, Dec 1913. (Author's note)

(2) G. LOIZEL, Recherches sur l'hérédité des caractères du pelage chez les lapins, *Comptes rendus de la Société de Biologie*, Feb 3, 1906 (Author's note)

front half of its body and half its head white, the rest of its body being dark-grey.

Saint-Yves MÉNARD mated a white Russian buck-rabbit with a silver-grey doe-rabbit and obtained black offspring.

These black rabbits when mated produced black young for 3 or 4 generations, but in the 5th generation one white rabbit with black feet was found in the litter; this was a case of atavism.

The author's experiments made in collaboration with Prof. BOUCHER yielded the following results:

1) A black buck-rabbit on being mated with a white doe-rabbit, produced: 2 black young, 1 dark silver-grey with white head.

2) Black buck-rabbit  $\times$  white doe-rabbit: 5 grey, 2 black.

3) A black rabbit resulting from experiment 1, on being mated with its dam (a white rabbit), produced 3 black and 1 white. The proportion of pigmented individuals was larger than that of the white; in the last case the young were  $\frac{3}{4}$  white rabbit blood and  $\frac{1}{4}$  black rabbit; in experiment 2 there was a throwback to fawn-grey. This atavism is proved by several other series of experiments made by the author and has been confirmed by COLLIN (1) who says he frequently saw little red rabbits resembling their grandfather amongst the white individuals of each litter resulting from the several matings of white doe-rabbits with black buck-rabbits.

BIRDS. — From 1893 to 1903, Gustav LOIZEL (2) studied the inheritance of plumage colour in the carrier-pigeons of the military pigeon-cot at Vaugirard and came to the following conclusions.

1) If 2 pigeons of similar plumage are mated, 85 % of the young birds will have the same plumage as their parents

2) If 2 pigeons of different plumage are mated, their progeny will vary, according to the mixtures, in the following proportions:

a) The mixture mottled blue gives: 62 % mottled birds; 37 % blue and 0.88 % with new plumage colours.

b) The mixture mottled red gives 42 % mottled birds; 46 % red; 12 % with new plumage colours

c) The blue-red mixture gives 13 % blue birds; 36 % red; 50 % with new plumage colours

d) The white-blue mixture gives: 36 % blue birds; 40 % white; 24 % of new plumage colours

e) The white-mottled mixture gives: 33 % mottled; 44 % white; 23 % with new plumage colours

Certain colours of plumage are dominant over others, thus mottled is dominant over blue, red over blue, and white over blue and mottled.

The progeny of the same pair, generally remains the same every year, at least for 4 consecutive years, when the parents and grandparents had the same plumage.

(1) G. COLLIN, *Traité de Physiologie*, 2nd edition, Vol II, p. 701 (Author's note)

(2) LOIZEL, *Études sur l'hérédité de la coloration du plumage chez les pigeons voyageurs* Comptes rendus de la Société de Biologie, Mar 11 1905 (Author's note)

The plumage colour of the young birds differs every year, however, when the parents have plumage of different colours.

If the genealogy of given pairs is followed for a certain number of generations, new colours are sometimes found to occur without the possibility of tracing them in the progenitors, even as far back as the 8th generation.

As a result of his numerous observations, the author concludes that "colour like every other character depends upon the parents' capacity of transmission, but some colours such as chestnut and grey in the case of horses are more easily transmitted".

When animals are the result of hybridisation or crosses between individuals of different breeds, there is no fixed rule as to colour-transmission and atavistic colours may occur to such an extent that colour-inheritance is in abeyance.

When however the breeds have long been subject to selection, and great care has been taken to insure uniform coat colour, as is the case with many breeds of cattle, the results are perfectly certain.

Coat colour resembles all other characters: the greater the number of the generations, the more likely it is that the organism will be imbued with the breed elements and the less the risk of any new characters arising, provided the environment remains the same " F. D

284 - **Mutations observed in the Skunk (*Mephitis pudita* and *M. hudsonica*) in the United States.** - DILLFUS, J. A. (Laboratory of Genetics, Illinois Agricultural Experiment Station) and HOB BROOK, F. M. (Skunk Development Bureau, White Plains, N. Y.), in *Journal of Heredity*, Vol. XII, No. 6, pp. 243-254, figs. 5, Washington, 1921

The authors give a short account of the fur trade in the United States which has increased during the last 10 years to such an extent that instead of exporting raw furs to Europe, America is even in a position to import skins to be dressed and made up in the country. One important source of the native supply is the skunk (*Mephitis* spp.) (1) which is bred in captivity or in a state of semi-domestication. The authors then describe their experiments in skunk breeding, the mutations obtained and their hereditary behaviour.

So far they have discovered 12 mutations in *M. pudita*, and 3 in *M. hudsonica*. Mutations are evidently fairly frequent in this genus, and have also been observed in skunks captured in various States. There are 5 distinct types of mutation: 1) self-black; 2) seal-brown white with stripes; 3) black-eyed white; 4) white with a small amount of pigment in eyes; 5) pure albino. The 3 different albinotic types represent simple changes in single genes and therefore each gives a monohybrid ratio when crossed with the wild form. There is no evidence that they may be multiple allelomorphs. The appearance of mutations is increased by in-breeding.

There was a great preponderance of females among the skunks born (37 out of 56). F. D

285 - **Measurement of the Cutaneous Surface of the Horse.** — ROUSSY, B., in *Comptes rendus de l'Académie des Sciences*, Vol. 174, No. 3, pp. 195-196, fig. 1. Paris, January 16, 1922.

From measuring the surface of the human body, the author discovered the "geometric law":

$$S = H^m \times P^m$$

where  $S$  represents the body surface,  $H^m$  the mean peripheral height and  $P^m$  the mean perimeter.

## LOI GÉOMÉTRIQUE DE LA SURFACE TOTALE "S<sup>totale</sup>" DU CHEVAL

PAR LE DOCTEUR B. ROUSSY

Although convinced that this law is general, that is to say applicable to all measurable bodies, he wished to test it also upon quadrupeds beginning with the horse.

His first experiments were made on a small artificial horse and the results tested by covering the living animal with an artificial skin, which was afterwards removed, the pieces being laid out on a flat surface and their plane area determined; sometimes they were photographed.

In this way, he obtained a total measured surface of 54.37 dm<sup>2</sup>, as against 54.40 dm<sup>2</sup> calculated according to the geometric law. The results thus practically agree, the difference being only 3 cm<sup>2</sup>.

The examination of the appended figure will explain the processes by which the "geometric law" was evolved.

**DETERMINATION OF THE MEAN PERIMETER  $P^m$ .** — With a flexible accurate measuring-tape properly applied measure the perimeters alternately of the flattest and the most rounded contours of the head, neck, trunk, one hind-leg, and one fore-leg, as is shown by the dotted lines. In this manner, are obtained 15 perimeters numbered 1-15.

The measurements 10 and 15 are those of the lower border of the left side of both hoofs.

In order to obtain the measurements for the two other limbs, double the perimeters 6 to 15 inclusive. The sum of the 15 perimeters, 5373 mm. divided by their number (15) will give the mean perimeter  $P^m$  which is 358 mm.

**DETERMINATION OF THE MEAN PERIPHERAL HEIGHT  $H^m$**  — Measure (following all the curves of the skin), the chief out lines  $A$  ( $C$ ) and the line  $B$  drawn along the middle of the lateral surface of the animal, and then measure the three small lines  $a$   $b$   $c$  on the left fore-leg.

The sum of these 6 lines (4439 mm. in the given case), on being divided by 3 (the common divisor of the two series of lines), gives the *mean peripheral height*  $H^m$  which is 1480 mm.

The surface  $S$  of the horse is  $P^m \times H^m = 358 \times 1480 = 5289 \text{ dm}^2$ .

This result being very satisfactory might be adopted. If however desired, the negligible sum, 142 Sq. dm.(s) of the small surfaces of the ears, tail and soles of hoofs can be added (as was done above), and this gives the total surface ( $S^{\text{total}}$ ) of 5440 Sq. dm. F. D.

286 — **Characters of the Chilean Horse.** — CORREA, A. V., JETELLIER, M., IVAN DE D. RODRIGUEZ, VIAL, D. G., in *El Agricultor, Revista de la Sociedad Nacional de Agricultura (Chile)* Vol. VI (Vol. 52 of the *Boletín*), p. 201, No. 10, Santiago de Chile, October 1921.

Report of the Commission appointed by the Managing Board of the National Society of Agriculture and approved by the Society at its meeting of 1 August 22, 1921.

**GENERAL CHARACTERISTICS.** — The Chilean horse belongs to a very muscular type; it is heavily-built, but agile, and its movements are swift.

The chest girth varies from 1.62 m. to 1.82 m. according to the animal's height which is from 1.35 m. to 1.50 m.

**CHARACTERS OF THE BREED.** — *colour* variegated; as a rule, the coat is of two distinct colours, or there is a little white on the forehead and legs.

*Skin* thick; little hair on fetlocks; mane and tail generally thick, hair wavy.

*Head* light, of medium length, forehead broad and flat, profile straight or slightly convex; eyes bright, slightly covered by the superciliary arch; ears small and mobile.

*Neck* of average length, wide at the base which is strongly joined to the scapula; slightly convex in the upper portion, full and nearly rectilinear in the lower, slender at its junction with the head.

*Withers* usually too low, short and buried in masses of muscle. It

is necessary to improve the withers with a view to the saddle ; they must be enlarged and made more prominent without the exaggeration seen in the pure-blood or hunter.

*Shoulder* very muscular but sometimes too short and too straight. Its slope and length must be increased in order to obtain the quickness of movement required in a saddle-horse.

*Chest* wide, muscular, shoulder-blades well separated.

*Back* very muscular, sometimes a little long and low where it joins the withers. It should always be strong and short (the length of the horse being obtained from a sufficient slope of the shoulders) with long withers, haunches and croup.

*Haunches* wide, muscular, strongly joined by a straight sometimes slightly convex line to the croup.

*Croup* long, full, slightly inclined. The tail is inserted rather low and is therefore generally pendent, or a little turned up at the lower part.

*Trunk* well-developed, ribs round, barrel cylindrical, and flanks short and full.

*Fore-legs* : fore-arm long straight, arm properly inclined, elbow free from chest, both very muscular ; knee strong and wide ; cannon-bone of average length relatively slender ; seen from the side it should be wide, sinews strong and standing well apart.

*Hind quarters* : haunch very muscular ; the croup must be long, the leg wide, muscular internally and externally, hock dry and strong, sometimes a little narrow from the front view. The wide space between the legs when the horse is in motion is characteristic of the breed. It denotes strength and energy but must not be exaggerated, for thus the harmony of the animals' movements is unpaired.

*Articulations* : small, round and very dry.

*Pasterns* : short, strong, must have sufficient slope to be very elastic.

*Hoof* : relatively small, high ; sole concave, frog little developed.

*Character* : Docile and a good worker.

#### DONKEYS

287 - **The Donkey of Catalonia, Spain.** -- ROSILL Y VILA, M. (Profesor de Zootecnia de la Escuela Superior de Agricultura, Madrid), in *El Cultivador moderno*, vol. VII, No. 1, pp. 3-5 figs. 3. Barcelona, January 1922.

The Catalonian donkey is a native breed, as can be seen from prehistoric drawings and the neolithic remains.

The chief characters peculiar to the breed are described exhaustively by the author. They are as follows : head with rectilinear outline in adult animals, with double frontal convexity in young individuals, brachycephalous in type 0.56 m. to 0.68 m. in length ; ears straight and long (0.38 m. to 0.42 m. in length) ; height 1.35 m.-1.65 m. ; neck slender ; shoulder not very sloping ; withers little raised and distinct ; dorsal line straight and long ; chest a little narrow but with spacious thoracic cavity ; chest walls moderately rounded ; croup short with double slope ; sacrum very prominent ; legs slender and strong. The coat of the adult donkey varies between chestnut and nearly black ; the axilla, the flat

portion of the thigh, lower part of chest and of the belly are all silvery white. The muzzle is white as far as the lower third of the nostrils and there is a white circle round the eye. Their harmonious shape, expressive faces and lively temperament give these donkeys a very handsome, high-bred appearance.

The measurements of a good specimen two years of age are as follows : height at withers 1.50 m. ; height at middle of back 1.46 m. ; length of back 1.45 m. ; girth of chest 1.60 m. ; circumference of tibia 22 cm. ; weight about 350 kg. The female donkeys give an extraordinary amount of milk, the lactation period is long and may even last 18 months ; from 4.5 to 5 litres of milk are given daily for a year, the amount decreasing to 2.5 litres at 18 months.

The jack-asses are chiefly used for the breeding of mules and must not be exported after they are 2 years old. Formerly they were exported practically to all parts of the world either for mule-breeding or to improve native races of donkeys in other countries. The price of a good breeding-animal is from 4 000 to 8 000 *pesetas*.

The Catalonian donkeys are of two types, the one inclining to height and the other to width ; the first are found in Comarca de Urgel and the second in Vich and Olot. The broad animals are preferred by the Italian and French importers and the tall by the English (for India, the African Colonies and Australia) and by the North Americans.

The " Mancomunidad de la Cataluña " (Association of all the political parties of Catalonia) (1) has started a stud-book for donkeys in which the only entries are of breeding-animals which have gained prizes at the shows held by the " Mancomunidad " or the progeny of the prize-winners.

F. D.

288 - The Cattle Industry of Cuba. NINETEEN in *The Cuban Review*, Vol XIX, No. 9, pp 13-16, Aug. 18 New York August 1921

CATTLE

Cuba is admirably suited to cattle-rearing. The climate is temperate and the temperature varies little which allows of the animals to be left in open pasture all the year round. Care must however be taken during the summer rainy season to remove the cattle from the low wet lands to the adjoining higher country, otherwise foot-trouble may result from the animals being continually in the water. In the dry season of winter, when grass begins to get short and scarce, and water hard to obtain on the higher better-drained areas of the interior, the cattle have to be brought down to the moist pastures at lower levels. Good water is practically obtainable everywhere throughout the Island, especially in the centre of the Provinces of Camagüey and Oriente.

Guinea Grass (*Panicum maximum*) and Para Grass (*Panicum molle*), have been introduced into Cuba and grow luxuriantly, furnishing the best

(1) The " Dirección de los Servicios de ganadería de la Mancomunidad de Cataluña, Calle Urgel, 87, Barcelona ", will furnish information on all subjects connected with Stock-breeding in Catalonia. (Ed)

of pastures, especially for fattening purposes. The former plant prefers the higher lands, the latter does best on the lower. Excessively close grazing will, however, destroy them and their places are taken by the native grasses of Cuba, of which the principal, "espartillo", is an excellent forage plant highly prized for milk production.

The topography of Cuba is favourable to the combination of agriculture with cattle-raising. In the Province of Pinar del Rio, in the southern portion of the Province of Santa Clara, in the northern portion of Camagüey, and throughout a very large area of the Province of Oriente, slightly undulating areas of agricultural land are found bounded by rough broken country in many places still covered with virgin forest, but where the trees have been felled, the slopes are all covered with tall rank grass composed of *Panicum maximum* and *P. molle*.

At the end of the War of Independence, the cattle industry had practically disappeared, but very soon large quantities of stock were imported from Florida, Texas, Mexico, Central America, Panama and Venezuela, and the supply exceeded the demand; this continued for some years.

In 1915 however many stock-breeders began ploughing up their pastures and planting them with sugar-cane. This change though slow at first, gradually became more rapid and reached its climax in the spring and early summer of 1920. The necessary results were a decrease in cattle production and increased importation.

Thus while from 1907 to about 1919, only breeding stock were imported, some 20 000 head of cattle were introduced in the 2 following years, the animals coming chiefly from Venezuela, Colombia and Costa Rica; a few have recently been imported from the United States. The animals imported after the War of Independence constituted, with their offspring, what might be called the native breed of cattle. They still exist in countless herds and are of a non-descript heterogeneous type. They are, however, being improved by progressive breeders through the introduction of high-class pedigree sires of the Polled Angus, Hereford, Durham and Zebu breeds.

Some cattle-raisers greatly prize the Polled Angus race, as it has proved able to adapt itself to the climatic conditions of Cuba-is resistant to ticks and diseases, and produces fine beef-cattle.

The Hereford is also favoured, but is regarded by some breeders as a lazy animal which does not make full use of the grazing-ground.

The Zebu is perhaps the greatest favourite; it is almost tick immune, of good form and excellent as a beef animal.

As a result of the introduction of the Zebu and the Polled Angus, a vast number of cattle have been improved, the animals being heavier and producing meat of better quality.

The large Cuban sugar crop is hauled from the field to the railway loading stations in carts drawn by oxen of which 3 to 5 yokes are required for each cart. Assuming the annual amount of cane transported to be 36 360 000 long tons, it takes about 8 million cartages to haul it, each cart-load being 4 5 tons. Thus a great number of cattle are needed for

the work and it would be advisable to raise special breeds for the purpose. Among the favourites adopted by the Cubans almost from their first introduction has been a strain from Porto Rico consisting of heavy animals, of excellent disposition, easily trained and taking readily to the work. Certain types of Colombian and Venezuelan cattle have been found to be well adapted for use in carts. Cattle with a certain amount of zebu blood are much faster than the other strains used, but their wildness and the consequent difficulty in handling them is a great drawback.

The law requires that all cattle imported into the Island from South and Central America, Mexico and Texas should be dipped (to free them from ticks) at the port of introduction. In nearly all the better ranches of the interior, dipping has been adopted as the best means of getting rid of tick, but it is not compulsory. The subdivision of pastures and the systematic transfer of cattle from one subdivision to another with a view to the complete eradication of ticks has not yet been adopted.

The raising of stock in connection with the sugar-mills has not been fully developed.

The estimated consumption of cattle in Cuba is about 1000 head per day. Modern up-to-date abattoirs are rare in the Island; there is one at Camaguey and other at Havana. An attempt has been made to instal refrigerating plants, but without success for the Cuban has a prejudice against refrigerated meat, and when meat has been kept on ice at the butcher's it has to be sold as second grade meat.

The acreage under sugar-cane will probably decrease, which will result in an increase in the land available for pasture and hence in the number of cattle raised. A tremendous drop has already taken place in the price of cattle. Yearlings which fetched at least 45 dollars per head in 1920, could be bought for 15 dollars in the second half of 1921. F. D.

289 - **Improvement of Dairy Cattle by Milk Control in Denmark.** - FABER, A (Agricultural Commissioner to the British Government), in *The Journal of the Ministry of Agriculture*, Vol XXVIII, No 7, pp 598-602, figs 1, No 8, pp 701-711, figs 2. London October and November 1921.

The first Danish Milk Recording Society was instituted at Vejen, in 1895 under the name of "Vejen Kontrolforening". The aim of this society was to ascertain the quantity and quality of the milk yield of individual cows in order to be able to eliminate the animals that did not pay for their keep and to reserve the best cows for breeding purposes. When the Vejen Society had been working for a year, it was found that the best of the controlled cows produced a pound of butter at the cost of 6d and the poorest cow produced a pound of butter at the cost of 2s 8d.

By the Law of 1902 the Danish Government made a grant not exceeding £10 to each Milk Recording Society of at least 10 members with 200 cows, on condition that the Societies should help to form better strains of dairy cattle. This grant was renewed by the Law of 1912.

The results of the institution of Milk Control Societies were: an increase in the general average of milk production, the adoption of a more

liberal teeding for cows, a selection of breeding-animals based, not as before, on external conformation alone but also on an exact knowledge of the quantity and quality of the milk produced and on the ability of the cow to transmit her character as a milk producer to her progeny.

The good results obtained by these Societies are shown by the records of those of Funen. These were founded in 1899-1900, in which year they controlled 5467 cows, the number rising in 1915-1916 to 40 116. The average annual milk yields of all the cows (whether in milk or not) belonging to the Societies being for these two years, 6 822 lb. and 7 938 lb. respectively; the fat percentage being 3.36 and 3.55, and the butter yield 255 lb. and 323 lb. respectively.

The Danish dairy farmer breeds his own cattle; he adopts in-breeding or line-breeding, thereby forming families.

Family herd-books are a special feature of Danish cattle-breeding, their value depending to a great extent on the work of the milk-recording societies. These herd-books have proved that the greater the number of high yielding animals a cow can count among her ancestors, the more likely she is to transmit the quality of high yield to her offspring. The author reproduces two specimen pages of the Book of Record Sheets on which are entered not only the cows' performance but also details relating to her ancestry and progeny. The family herd-books are not drawn up by the Controller of the Milk Recording Societies, but by the Agricultural Advisers appointed by the Agricultural Societies or the Joint Committees of Breeding and Milk Recording Societies. The State pays part of the salaries of these advisers.

About 1880 official herdbooks were started which are to some extent based on the family herd-books. These official herdbooks give the description and pedigree of the animal, as well as the milk and butter production in the case of a cow, and the performance of its female progenitors in that of a bull.

In order to find herds which not only contained prominent animals but consisted of families from which a good supply of breeding stock could be obtained for the improvement of other herds, competitions were carried out for one year at a time; later, these competitions lasted two years. The first was held in Funen in 1894-1896 and the 7th in 1913-1915. Another series was begun in Sealand in 1897. The best herds were officially recognised as "Breeding Centres".

The results obtained at Funen were as follows: 1st *biennial competition*: 7 competing herds consisting of 530 cows: average annual milk production per head 697 gallons, fat percentage 3.44 — 4th *competition*: 18 herds 777 cows, 853 gallons of milk, at percentage 3.53 — 7th *competition*: 10 herds, 304 cows, 934 gallons of milk, fat percentage 3.83. These competitions between entire herds are a peculiarity of Danish cattle-breeding. The Government encouraged them by annual grants.

An important step forward was made when it was ascertained from the records of the Milk Recording Societies that the capacity of yielding

large quantities of milk with a high fat percentage can be transmitted through the bull to his progeny.

By the Laws on Breeding Domestic Animals (1887 and 1902) grants were made by the Government for prizes for bulls at District Agricultural Shows, under the conditions that the animals were to be kept for service in the country at least until May 1st in the following year and that bulls 5 years old or older should be judged through their offspring. This second proviso gave rise to "Offspring Shows" which are also a special Danish feature. By these means farmers have for a number of years been encouraged to preserve good bulls for service. While in 1887, only 371 bulls were presented at the District Shows, in 1908 more than 1200 were presented at the State Shows, and as many as 250 old bulls are entered at local shows every year.

The law of 1902 offered a further grant of £750 to cattle breeding societies "which by showing superior offspring have proved to be particularly capable of developing good strains of dairy cattle." In order to participate in this grant, the Breeding Societies must exhibit at the Offspring Shows their bulls and  $\frac{1}{8}$  of the total number of their cows, and at least 2 bulls and 24 cows. One fourth of the cows must be between one and two years old and for  $\frac{1}{4}$  at least, two years' milk records must be produced. Breeding Societies have an additional claim to the grant if they have formed or are about to form tribes or families of dairy cattle producing a high yield of butter. When the Law was amended in 1912, further encouragement was offered to cattle-breeding societies having many of their cows under the control of the milk-recording societies. A grant is offered for each bull belonging to a cattle-breeding society when the bull is at least 1  $\frac{1}{2}$  years old and has been awarded certain prizes at shows; the amount of the grant varies according to the proportion of the cows belonging to the breeding society that are being reliably controlled as to their yield of milk, butter production and consumption of fodder.

When the Milk Recording Societies had worked for a considerable number of years and had on their books some 15 000 herds including 250 000 cows or about  $\frac{1}{5}$  of all the cows in the country, a large amount of information was available.

This statistical material was worked up by the Federations of Agricultural Societies. The investigations are now carried on to a large extent by the Officers of the Provincial Federations, the Government defraying part of the cost. These records are used to determine which of the registered bulls influence the milk yield of their progeny, so that it is higher than that of the dam of the bull. Butter production is taken into special account.

Both with the Red Danish Dairy Cattle and the Jutland Breed much of the progress during recent years is due to the influence of a few bulls having remarkably strong power of transmitting higher milk yielding capacity to their progeny.

The use of milk records in the breeding of cattle both by line-breeding and employing bulls selected as explained above, has now been carried

on long enough to show definite results; this is clearly seen by comparing the yield of the herds at two different periods.

Year	Yields of milk	Fat	Yields of butter
<i>Red Danish Breed.</i>			
1905 - 1906	8.941 lb.	3.58 %	356 lb.
1915 - 1916	10.041 "	4.11 "	4 602 "
1905 - 1906	9.427 "	3.40 "	356 "
1915 - 1916	11.282 "	4.30 "	546 "
<i>Jutland Breed.</i>			
1900 - 1901	5.315 lb.	3.09 %	183 lb.
1916 - 1917	8.175 "	3.87 "	354 "
1897 - 1898	5.922 "	3.01 "	196 "
1913 - 1914	8.538 "	3.84 "	367 "
<i>Shorthorns.</i>			
1901 - 1902	6.864 lb.	3.62 %	277 lb.
1911 - 1912	10.164 "	4.06 "	460 "

Averaging 18 herds of all 3 breeds during a period of about 14 years, the milk yield has been increased 26 % and the butter production over 50 %. The improvement has been general throughout the country and is not confined to the stock of eminent breeders, but extends also to that of small farmers. In the opinion of MÖRKEBERG: "the capacity to yield much milk and the capacity to yield rich milk are two different characters, both hereditary, but inherited the one independently of the other." If this is correct, the problem is still easier for a country where a high milk yield is the main object, than for Denmark, where a large production of butter is required.

The rules for Cattle Shows vary a little in the different Provinces; the author quotes as instances some of the rules for the provincial Shows held by the Associated Agricultural Societies in Funen. F. D.

290 - **The Utilisation for Grazing-Grounds of the De-forested Lands of the South of the United States.** -- FARLEY F. W., and GREENE, S. W. (Animal Husbandry Division, Bureau of Animal Industry, U. S. Department of Agriculture) in *United States Department of Agriculture, Bulletin No. 827*, 51 pp., figs. 13. Washington 1921.

The authors, give an account of the cattle-rearing conditions existing in the coastal plain of the South-East of the United States and the value as grazing grounds of the land formerly covered with pine-forests. They describe, the conditions of the climate and soil; system of land tenure; pastures; methods of feeding the cattle; building and shelters for stock; diseases and pests; water supply; the condition of the markets.

At the present time the area of this region (which includes the south-eastern portion of South Carolina, most of Florida, the southern part of Georgia, Alabama, and Mississippi, the central and northern part of Louisiana and parts of south-eastern Texas and of southern Arkansas, is estimated at 100 000 000 acres, and is being increased by about 10 000 000 acres annually as additional land is "cut over". The sandy soil is of sedimentary origin and is the natural habitat of the long-leaf yellow pine (*Pinus palustris*). Although the cattle industry has been growing rapidly since 1910, it has not developed to the full extent possible. The animals are of poor quality owing to various causes, but especially to the cattle tick which makes it impossible to keep pure-bred or grade animals in this district. Mature cows average about 400 or 500 lb. and steers of 3 to 5 years of age average from 600 to 750 lb.

The most important stock-breeding problem is the improvement of the pastures which can be effected by the distribution and protection of *Lespedeza* (Japanese clover), and of *Axonopus compressus* (carpet-grass). The native pastures furnish good grazing from early spring until about July; later, the quality of the grass deteriorates and in the winter, forage has to be fed to the cattle. Amongst the winter feeds the author recommends (as bulky fodder), maize stalks, hay made from leguminosae, cotton seed meal and maize silage (as concentrates), velvet-beans (*Stizolobium* sp.) in the pod.

The author gives the results of a feeding-experiment in which the Mississippi Experiment Station collaborated. This experiment has shown that the same increase of live-weight, at the same cost is obtained by feeding the cattle on maize silage or velvet-bean pods whether crushed or whole. The animals, however, eat the whole pods more readily.

F. D.

291 - **The Value of Beet Molasses in the Ration for Fattening Steers.** GRAY, A. S. in *Facts About Sugar*, Vol. XIII, No. 6, pp. 112-113. New York, August 6, 1921.

An experiment has recently been carried out by the Iowa Experiment Station at Ames with a view to determining whether beet molasses or cane-molasses (both well-known to be excellent feeds for beef cattle), is the more efficient and economical.

Prof. EVVARD finds that when maize sells at 1.71 dollars per bushel, it is cheaper to feed molasses at 45 dollars per ton, but when maize is selling at 50 cents per bushel and 30 dollars per ton is paid for molasses (as in the United States, in 1921) molasses is too expensive.

The experiment was carried out with 5 lots of grade Hereford steers. Lot I which served as a control, received the standard maize-belt ration viz. (for the entire period), 21 lb. shelled maize + 10 lb. maize silage, 5 lb. mixed timothy and clover hay + 3 lb. linseed oil meal.

Lot II received in addition to the standard ration, 2 lb. cane molasses per head, per day but ate 2.5 lb. less maize, 2 lb. less silage, the same oil-meal and less hay than Lot I.

Lot III was fed the same ration as Lot I with the addition of 5 lb. cane

molasses. The animals received up to 8 lb. daily for a while, which was all they could consume, but the extra feed did them no particular good.

Lot IV got the regular ration with 2 lb. beet molasses added. Lot V was fed the standard ration plus 5 lb. beet molasses.

The experiment lasted 120 days. The initial weight of the steers was 1 000 lb. each and the range of weights at the end was 1356 to 1430 lb., the variation being due to the different rations.

The daily increase of live weight was 48 oz. per head and per day on the average for all the groups. All groups with the exception of the Vth showed less increase in weight than Lot I, which showed an increase of 49 oz. per head and per day, the increase for Lot V being just over 48 oz. Both gave a return of 61 % when killed, all the others proving less profitable.

Lot II, III and IV would in any case have showed inferior results to Lot I even if the molasses consumed had cost nothing. On the other hand Lot V, which consumed the maximum amount of beet molasses, made a better use of its food and shewed an increase in weight practically equal to that of Lot I, was sold for practically the same price per lb. of life-weight and as it consumed the least expensive ration really proved the most satisfactory. F. D

292 - **The Sterilisation of Cows.** I GAVARD, G., in *Recueil de Médecine vétérinaire*, Vol. XCVII, Nos. 22-24, pp. 429-433, Toulouse, November 30-December 30, 1921. — I BOUCHET, *Ibidem*, pp. 441-443.

I. After having tried for the sterilisation of cows the crushers of CHASSAIGNAC, FLOCARD and KREBS, BERTSCHY and DEGIVE's elastic ligatures, metallic ligatures, American forceps (all with unsatisfactory results), and also the ovariometers of BERTSCHY and FAVRE which gave better results, although all danger of haemorrhage was not eliminated, the author finally decided to adopt the HESS ovariometer (invented in 1912), which gave him complete satisfaction. Since 1913, he has used this instrument in the Canton of Geneva and the Departments of Haute Savoie and Ain, operating upon 700 to 800 cows annually without a single accident that could be attributed to the treatment.

The HESS ovariometer consists of a double metallic rod and of a movable rod sliding in the fixed part and provided at the end with a screw which is worked by a nut. The movable rod has at the end an oval ring bearing on either side a narrow process fitting into the corresponding slot-hole. A very ingenious type of guillotine is fixed to the apparatus and assists in cutting the neck between the ovary and the extreme limit of the crushed portions. A movable handle, that can be affixed to the rod according to the wish of the operator, gives a firm point of support which allows of great pressure being applied.

The advantage of this angiotribe is that it caused a double crushing and knife is independent and movable, working with a sliding motion, so as to cut outside the laminated margin.

II. — BOUCHET has presented to the Central Society of Veterinary Medicine an ovariometer invented by himself.

This instrument consists of two parts acting as a crusher, that is to say, of a groove in which slides a wormed rod which is drawn down by a nut. At the opposite end, the groove and the screw are both provided with a very wide expansion containing an aperture 50 mm. by 60 mm. through which an ovary can pass. These two apertures correspond when the instrument is open. On moving the nut, the screw is drawn down and with it the aperture at the end of it. This opening then slides in front of the aperture at the end of the groove which remains fixed. This displacement constricts the neck of the ovary which is soon compressed and crushed between the sides of the apertures. These are provided with a projecting ledge furnished with small oblique and opposite incisions forming the two jaws between which the neck is ground. At the extreme limit of their course, the ovary is detached by a blade that only comes into operation after the compressed bundle is crushed.

293 - **Possibility of Increasing the Milk Yield of the Charolais Breed.** CHARON, AD J in *Journal d'Agriculture pratique*, Vol. I, No. 3, pp. 80-81. Paris, January 28, 1922.

On January 15 and 16, 1922, a Cattle Show was held at Charolles by the Breeders' Society and the Agricultural Society of the Department of Saône-et-Loire; 150 Charolais cattle, most of them magnificent specimens, were exhibited and proved the remarkable results obtained by selection. The extreme breadth of back, great development of the rump and the width of the hind quarters, all characteristics of the Charolais breed, were accentuated more each year.

Further, there is every possibility of increasing the hitherto low milk-yield of the cows. In fact, nearly all the cows exhibited by one breeder, which were as fine as any of those exhibited, had an extra teat, which is a sign that a milch-cow line could be evolved within the breed.

294 - **Sheep-Rearing on Temporary Pastures in the United States.**— MARSHALL, F. R. and POTTS, C. G., in *United States Department of Agriculture, Farmers' Bulletin* 1181, 16 pp., figs. 7. Washington, 1921.

The authors show the economic advantage of temporary pasture in the case of sheep-farms, and describe the systems adopted at the Experimental Farm, at Beltsville (Maryland), where the sheep are turned out at the beginning of April to graze on a field of barley, or rye, and in the summer and autumn are grazed on forage consisting respectively of lucerne, oats and peas, colza, soy-beans and maize; "velvet beans" (*Stizolobium* sp.). These forage crops, which last one year, cover 12 hectares: 20 ares supply on an average 250 grazing-days for 1 sheep. The fields are divided up into plots in each of which the sheep are kept for 14 consecutive days, but not longer. It is advisable for these plots to be rather narrow, so that they can easily be subdivided by small, movable hurdles.

Such a temporary ley, not only supplies food for a greater number of sheep per acre than permanent pasture on equally fertile soil, but it allows the grazing ground to be more frequently changed thus dimin-

ishing the danger of infestation by intestinal worms and other internal parasites.

Further, the temporary pasture as compared with the permanent pasture induces a more abundant milk supply which is more uniformly distributed during the lactation period.

It is wise to cultivate wheat if possible rather than rye, as it makes a better spring fodder. Oats and peas mixed are excellent, although on rich soil, colza makes the cheapest pasturage for sheep. Where the soil is not deep, it should be sown with soy-beans. The sheep may be left out on grass from July until the first frosts.

Lucerne and melilot make excellent toddlers for sheep; especially if precautions are taken to avoid flatulence. F. D.

295 - **Experiments in Rearing Sheep and Goats in the United States.** — I JONES, J M, BREWER, R A and DICKSON, R E, Grain Sorghums Versus Corn for Fattening Lambs, in *Texas Agricultural Experiment Station, Bulletin No 260*, p 13 College Station, 1920 — II MAGLE, W T and DARLOW, A E, Sheep Feeding Investigations, in *Oklahoma Agricultural and Mechanical College, Agricultural Experiment Station Bulletin No 133* Stillwater, Okla., 1920 — III MILLER, F C (Sheep Extension Specialist, University of Kentucky), Facts that Sheepmen Desire to Know, in *The Breeder's Gazette*, Vol LXXI, No 5 2095, pp 139 140 Chicago, February 2, 1922

I. GRAIN SORGHUMS VERSUS MAIZE FOR FATTENING LAMBS — Feeding experiments carried out for 90 days and begun on November 26, 1919. Six lots of 20 lambs of the average weight of 59.42 lb were used. In all 6 lots, each lamb received an average ration of 1.08 lb. grain, 0.14 lb. cottonseed meal and 1.89 lb. lucerne hay. The grain fed each lot was respectively: 1) ground milo heads; 2) ground threshed feterita; 3) ground maize; 4) ground threshed milo; 5) ground feterita heads; 6) ground threshed kafir. The average daily increase in weight of the 6 groups per head and per day was respectively 0.362 — 0.36 — 0.393 — 0.394 — 0.339 — 0.372 lb. In order to obtain 100 lb gain the 6 groups consumed respectively: 337.01 — 338.66 — 310.43 — 309.89 — 359.99 — 327.75 lb. of grain + cotton-seed meal 523.02 — 525.60 — 481.76 — 480.94 — 558.68 and 508.65 lb. of hay.

The authors give the analysis of the foods used and their productive value calculated according to FRAPS' system (1).

(1) See: G S FRAPS, The Production Coefficients of Feeds in *Texas Agricultural Experiment Station Bulletin* 185, 1916. The value of a feed is measured by the volume which satisfies the appetite of the animal, the content of digestible protein furnishing the material for rebuilding or repairing the muscular tissues, etc., and by its "productive value" which is its value as a source of energy capable of being transformed into internal or external work, heat, fat, etc. This Bulletin describes the method suggested by FRAPS for calculating the productive values of feeds from their chemical composition.

The productive value of a food is defined as follows: the amount of fat which this food would produce in the case of an animal that is being fattened, if it were fed in addition to a basal ration sufficient for the requirements of the organism. The author prefers calculating the productive value in terms of fat, because fat most nearly represents the substance actually measured in the experiments and by adopting this method, there is no need to have

The productive values of the rations used were respectively 16.3 — 20.6 — 20.3 — 18.5 — 16.0 — 14.4.

Lot IV made a slightly larger, but much more economical gain than Lot III, the net profit being 2.73 dollars per head in Lot IV while it was only 1.70 in Lot III.

Lot I made a slightly larger and much more economical gain though Lot V approached very closely.

Ground milo heads (Lot I) give a slightly lower increase in live-weight than ground threshed milo, but were more economical.

This test proved conclusively that for fattening lambs maize shipped into Texas cannot successfully compete with the grain sorghums of the semi-arid sections of Texas which are so well adapted to the production of these non-saccharine sorghums.

## II. COMPARATIVE RATIONS FOR FATTENING CASTRATED LAMBS. —

The feeding experiment began on November 20 and lasted 96 days; the experiment with Lot II was suspended after 70 days. No loss was occasioned by the liberal ration of cotton seed cake. Lot I which was fed a smaller amount did well on the ration until the end of the experiment. From the results summarised in the following Table, it must be concluded that the heads of kafir (a variety of sorghum), are too bulky a feed for lambs. Lot IV (22 lambs) fed on kafir grain yielded a net profit of 10.34 dollars above that obtained from Lot III (22 lambs) which were given kafir heads. The most important result of the experiment was the discovery that the use of silaged darso (a variety of sorghum), reduced the cost of the increase in live-weight. This is seen by comparing Lots III and IV, which were given darso silage, with Lot V which had none.

## III. EXPERIMENTS IN FEEDING AND BREEDING SHEEP AND GOATS. —

The experimental work in sheep husbandry was begun by the Bureau

recourse to any hypothesis as to the amount of productive energy used in the formation of fat, or to any other hypotheses. When the composition and digestibility coefficients are known, it is possible to estimate the fat-producing value of a given food, but in order to simplify the calculation, FRAPS suggests the use of a factor called the "digestibility coefficient", which may be defined as follows: "the factor which multiplied by the food percentage gives the productive value of this food expressed in terms of fat." As the productive coefficient is calculated from the coefficient of digestibility, all that influences digestion also influences the productive coefficient. In the same way, some foods may be regarded as mixtures of two or more ingredients with different digestibility coefficients and different productive values. Non-decorticated cottonseed cake may for instance be regarded as being the residuum of the decorticated seeds plus the integuments of the seeds; the amount of the latter can be estimated from the crude fibre present. Since decorticated seeds and their integuments have different productivity coefficients, the amount of crude fibre will affect the productive coefficient of the feed.

There are similar variations in the composition of other feeds which depend on their different constituents which vary in digestibility and productive values. A table is given showing the productive coefficients based on the average coefficients of digestibility. One column shows the correction method employed for crude fibre, N-free extracts or for both, as occasion arises: — *Experiment Station Record*, Vol. XXXV, p. 561, 1916.

of Animal Industry of the United States in 1906, in collaboration with the Wyoming Experiment Station at Laramie. There are at present e sheep-farms (one at Beltsville Md., and one at Vienna Va.) where the Government is carrying on experimental work in breeding and flock management. The studies include . farm sheep — range sheep — wool and other animal fibres — milch-goat investigations.

The farm flock studies include sheep on temporary pastures, flushing (extra teeding of pregnant ewes) and other means of increasing lamb yields nutrition studies in the growth of sheep, type-fixing in Southdowns and improvement in length of staple and quality of Southdown fleeces.

*Results of Feeding Experiment with Castrated Lambs.  
Length of Experiment 96 Days*

Lots	Ration of Concentrates per head and per day	No. of lambs	Average initial weight per head		Average daily increase per head	Cottonseed cake	Kafir	Sudan Grass	Lucern: hay	Silaged darso
			kg.	gm		kg	kg	kg	kg	kg.
I	170 gm cottonseed cake	21	27.6	90	1.88	(1)	9.29	—	11.51	
II	250 gm cottonseed cake	22	26.4	97	2.58	(1)	8.32	—	9.76	
III	380 gm kafir head.	22	25.4	138	—	2.76	—	6.38	7.21	
IV	360 gm kafir grain . . . .	22	25.5	151	—	2.37	—	5.88	6.53	
V	410 gm. ground kafir . . .	21	26.4	152	—	3.00	—	9.98	—	

(1) Small quantities of kafir were given during the last 18 days of the experiment.

Many good shepherds practise flushing ewes both before and during the breeding season, others, however, do not believe that the advantages are sufficient to justify the practice. In order to throw some light on the question, the Bureau of Animal Industry made an experiment at Beltsville Farm. A total of 302 matings have been studied with the following results. The value of flushing comes largely from the increasing number of turns; 78 % of the ewes with twins lambled in the first half of the lambing season and those that were in best condition were the first to come on heat.

Lamb yields were sufficiently increased to more than balance extra cost of food consumed. Dry feeds gave practically the same results as grass or other green feeds. Ewes given extra rations two weeks before the breeding season began, and throughout the mating season made an average gain of 3.2 kg. per head. At market age the twins averaged considerably less than the singles, but there was practically no difference between twins and singles when fully developed. Records failed to show that twin ewes were more prolific than singles.

Twin lambs do not fatten as early as singles if well nursed from birth.

The Bureau of Animal Industry is endeavouring to produce a type of Southdown uniform in colour markings, of large size and having a denser

fleece with a long staple. So far the light colour markings of the face and legs is practically fixed and the fleece is 20 % heavier and the staple longer than that of the foundation flock.

The range sheep investigation was begun in connection with the Wyoming Experiment Station and transferred later to the Federal Station at Idaho, where the Bureau is conducting experiments along 4 distinct lines as follows :

- 1) Breeding a type of Rambouillet with desirable mutton form.
- 2) Studying types of cross-bred sheep for the purpose of producing the type best suited to range conditions.
- 3) Comparing methods of utilising land for sheep-raising and methods of supplying water on dry ranges.
- 4) The production of crops on arid land that may be used for winter feeding of sheep.

Good results have already been obtained as regards the first problem, wool and mutton production having already been improved.

In 1914, a flock of Corriedale sheep were imported from New Zealand to serve as a foundation flock at the Dubois Station. The fleeces from their offspring now average about 10 lb. with a shrinkage of about 50 %. Much progress has been made in adapting these sheep to the ranges of the Western States of the Union.

Ewes of the Rambouillet breed were crossed with rams of the long-wool breeds including Lincoln, Cotswold, Leicester and Komney-Marsh. After a few years experience with these rams the best Lincoln-Rambouillet rams were mated with the best ewes of the same cross and the progeny of this cross have received the name of Columbia.

Columbia lambs weigh 10 to 12 lb heavier at weaning time than Corriedales. Columbia sheep on the whole are noted for size, mutton conformation and strong constitution. The choicest offspring resulting from the mating of Corriedale rams and Lincoln-Rambouillet ewes have been selected for the Corriedale-Columbia cross. The offspring from this combination are superior to the Corriedale in size, conformation and constitution. The Government will continue this work in the hope of breeding a type superior to either the Corriedale or the Columbia. All these cross-bred types have the flocking instinct and are well adapted to range conditions.

On the 28 000 acre ranch near Dubois, 5 fields of 80 acres each and one of 320 acres have been fenced and are being studied as to carrying capacity and for comparison of grazing under fence versus open range conditions. These fields are reseeded and furnish much more feed than unfenced ranges.

Sunflower silage is said to be an excellent winter feed for sheep.

At the Vienna Station (Virginia) Dr. Cooper CURTIS has found that it is possible to rear a fine flock of sheep in districts infested with stomach worms if the sheep are drenched once a month with a bluestone solution. A 24 % solution is prepared and kept in tightly-stoppered bottles. When required for use, it is diluted with 20 times its volume of water. Three and a half ounces of the diluted solution are given to each sheep weighing

90 lb. or more, lambs of 40 lb. can be given 1 oz. and for each additional 10 lb of live weight,  $\frac{1}{2}$  oz. should be added. This treatment must be discontinued 2 weeks before lambing.

In 1919, experiments were made in crossing American female goats with pure-bred Saanen and Toggenburg males. The best native goats only give 1  $\frac{1}{2}$  lb. of milk daily but first cross goats gave on an average 3.15 lb a day. After 2 years, the animals gave 3.9 lb. per head per day and the lactation period lasted about 9 months. F. D.

## PIGS

296 — **Sorghum as a Pig Food.** — POULAIN, A in *Journal d'Agriculture pratique*, Vol. II, No 47, p 138. Paris, November 26, 1921.

As the result of experiments made at the piggery of the Experiment Centre of Fontmarie (Bouches-du-Rhône), the author arrived at the following conclusions.

*Physiological effects.* — Judging from the excrement, sorghum is one of the most cooling foods. It has the rare virtue of permitting the systematic use of peanut cake and the forcing of development without undue strain on the organism.

*Feeding sows.* — After trying various mixtures of sorghum, wheat bran and peanut cake, the author adopted the following: sorghum 66 % + bran 22 % + peanut cake 12 %, fed in the proportion of 2 % of the weight of the animals and supplemented by a grass ration of the same weight.

Nursing-sows receive an extra meal varying according to the number and age of the litter. With these rations the average weight at birth of the young pigs in a litter of 10 is 1 300 kg. in the case of hybrid sows (Marseillais Large White Yorkshires), the average weight usually being 1,200 kg. The conditions are evidently favourable for lactic secretion and the growth of the piglings, since litters of 7 or more weigh on an average 7 kg. at the age of 1 month.

*Feeding of young pigs.* — 1) Before weaning, little pigs living in the open do best on a mixture of 70 % sorghum + 30 % sharps. They will eat it from the third week; and a litter fed with this mixture will weigh 14 to 17 kg. at the end of 60 days with a graduated ration of 0 to 600 gm. per day (0 at the beginning and 600 at the end when they are weaned) only limited by the appetite of the piglings.

2) *After weaning.* The transition period is bridged over without any danger to the animals if peanut cake is added in the proportion of 20 % of the weight of the sorghum.

A daily ration of 1200 gm of sorghum + 400 gm bran + 300 gr. peanut cake fed to animals weighing 40 kg. has increased their weight 410 gm to 500 gm. per day in the case of breeding animals of the pure Marseillais race or crossed with Large Whites. The rations were given 3 times a day and the pigs were turned out into a yard for exercise after each meal.

From these experiments it may be gathered that sorghum mixed with peanut cake in the proportion of 4 : 1 can be substituted advantageously for palm-oil cake. This mixture added to sharps seems to be one

of the best in the climate of Southern France for rearing pigs, until the fattening period. F. D.

297 - **Suggestions with a View to the better Notation of the Shape of the Silkworm Cocoon and of Its Variations.** - PIGORINI, I. (R. Stazione Bacologica Sperimentale di Padova), in *Informazioni seriche*, Vol VIII, No 22, pp 333-334, fig. 3 Rome, November 20, 1921

SERICULTURE

The author in the course of his crossing experiments begun in 1919, found it necessary for the better notation of the shape of the cocoon to substitute for the description and the absolute figures giving the dimensions, the transverse diameter in the case of the cylindrical, ovoid, and spherical cocoons and the measures of the diameter of the inflations and of the constrictions in the constricted forms, these measures being always expressed in hundredth parts of the long diameter.

In continuing his researches, the author realised that this notation, or "characteristic", was also insufficient, as it fails to indicate whether a cocoon is spherical or cylindrical in its median portion, the greater or less distance of the inflations from the poles in constricted cocoons, etc.

The author proposes to continue to express the longitudinal diameter by 100 and to mark off (in hundredths of the longitudinal axis), the transverse diameters at given distances on the long axis. This second measure is expressed by a factor having as its numerator a figure giving the decimal division on which is marked the transverse diameter, whereas the denominator gives the value of this diameter. In the case of symmetrical cocoons, 5 notations are made, at 10-20-30-40-50 centimeters respectively of the longitudinal axis; in that of asymmetrical cocoons, 10 notations are made, one at every 10 centimeters of the longitudinal axis.

In order to make these determinations, it is necessary to project the magnified image of these cocoons upon a screen and from this image which is outlined in pencil, the measurements are taken. In this manner the author obtained for 2 commercial crosses, the data given in the following Table.

*Transverse Diameters of the Cocoons of Two Commercial Crosses*

Position of the transverse diameter on the longitudinal diameter	Gold Chinese	Yellow native	Cross Chinese Gold x Yellow native	White Chinese	Semi-spherical native	Cross white Chinese x Semi-spherical native
10	46.4	38.6	39.6	45.8	46.8	41.7

These data show that in the cross Gold Chinese  $\times$  Yellow native, the cocoons are intermediate in shape between the those of the parents, whereas in the cross White Chinese  $\times$  semi-spherical native, the cocoon tends towards a new type in which the transverse diameters are reduced as compared with the longitudinal diameter and constriction makes its appearance.

298 - A Simple Method of Obtaining Several Generations of Silkworms in the Same Year (1). — DE ZULUETA, A, in *Boletín del Museo Pedagógico de Ciencias naturales*, Vol I, No. 6, pp. 1-2, fig 1 Barcelona, March 1921

The author has succeeded in rearing 4 generations of strong silkworms by the adoption of the Japanese method which consists in getting the moths to deposit their eggs on paper and immersing both paper and eggs (4 to 5 hours after the eggs are laid), for 5 seconds in water at 55° C (2). The eggs are then allowed to dry and kept in a warmish room.

The caterpillars hatch out at the end of 12 to 15 days. In this way the author obtained a 4th generation in December.

In the August rearings (2nd generation), care must be taken to keep the surroundings damp, in order to prevent the young mulberry leaves withering too quickly.

To obtain leaves for the 3rd generation it is necessary to prune the mulberry-trees a month before the young caterpillars hatch out, a plentiful supply of fresh leaves being thus obtained. Artificial heating is needed for rearing the 4th generation and the temperature must be kept at about 20° C.

299 - Crossing Experiments with Varieties of Silkworm Having Bivoltine Males, in Italy. — FIGORINI, L. (Direttore della R. Stazione bacologica sperimentale di Padova), in *Nuovi Annali del Ministro per l'Agricoltura*, Year I, No 1, pp 133-146 Rome, 1921

This paper is a continuation of the author's previous article entitled Crossing Experiments with Varieties of Silkworms having Bivoltine Females (3). As in the preceding case, the object of the author was not to arrive at general conclusions, but rather patiently to collect the materials that are the fruits of observations made with the greatest care and hence of undoubted value, and capable some day of forming the basis of researches undertaken to determine the laws governing the phenomena of hybridisation in *Bombyx mori*.

At the same time that the author was making his crosses the previous year with female bivoltines and annual males, he carried out reci-

(1) See. *Boletín de la Real Sociedad Española de Historia natural*, Vol XX, p. 300, and "Tomo del Cincuentario" of the same Society, pp 495-501

(2) It is even better to plunge the paper with the eggs first into warm water (54° C), then into cold (20° C) water, then repeat this process. Duration of each immersion 2-5 seconds. (Author's notes)

(3) See R. Sept. 1920, No 900 (Fd)

procal crosses with the same lots of cocoons ("Gran Sasso" and White Bivoltin excepted) viz. :

Golden Chinese female with greenish-white male bivoltine.

White Japanese female with bivoltine males, viz. greenish-white, with gibbous caterpillars, white Chinese, mixed white, yellow

Ascoli female with male bivoltines : white with gibbous caterpillars, white Chinese, mixed white, yellow.

In all 12 crosses. The caterpillars had been hatched the previous spring.

The new characters of the cocoons were the object of these researches viz. :

The size and shape, taking the total of the 780 cocoons resulting from the crosses

The colour, determined on 5 gms. of the outer silk and fibrin per cross.

The weight of the outer silk and fibrin, determined on 480 cocoons

Length of reelable silk and standard, determined on 390 spun cocoons.

Strength and elasticity, determined on the silk of 195 cocoons (1264 determinations),

Three out of the 9 characters studied behaved in the same manner in the two sets of crosses (bivoltine female  $\times$  annual male and the reciprocal crosses), while 6 behaved differently in both cases. If we add to these characters that of bivoltism, which persisted in the first case, but was lost in the second, it is evident that by transposing the males and the females in the crosses, very dissimilar products are obtained, since most of the characters behaved differently in the two cases.

The size of the cocoons and the amount of crude fibrin in the raw silk were characters behaving in a similar manner in both kinds of crosses, being intermediate and attaining the average. On the other hand, two other characters that were linked with them in the female bivoltine crosses were separate in the male bivoltine crosses. One of these is shape, which had attained the average in the preceding crosses, only deviating from it in the direction of the shape of the strangled parent independently of its sex. Thus the character "strangled" is the dominant. The other is the standard; this is considerably higher than the calculated average and shows a distinct inclination to approach that of the annual females. There were two intermediate characters, but they were below the average and inclined to the maternal character observed in the female bivoltine crosses viz., the weight of the outer silk, and the length of the reelable silk. Neither can be classed in the same manner in the present crosses. It is true they remained intermediate and different from the average; in one of them, however, the weight of the outer silk still inclines towards the maternal character, but has risen a little above the average, whereas the in other, the length of the reelable silk has fallen below it, but shows an inclination towards the paternal character. As the length of the reelable silk was less in bivoltine than in annual silkworms, it must be concluded that this character has been affected by the bivoltine parent in the crosses.

The author found that in female bivoltine crosses one character, the strength of the silk, was intermediate, deviating from the average, being higher and showing a tendency towards the paternal character.

In the male bivoltine crosses strength of silk remained intermediate and above the average, but since the greatest degree of strength is a character distinguishing annual breeds to which the females belonged in these experiments, it may safely be said that it is the annual breeds with their "stronger tenacity" that have been dominant in determining the strength of silk of the hybrids. The elasticity remained such as it was in the female bivoltine crosses viz., a non-intermediate character greater than in the case of either parent.

The question of colour is more complex. In the female bivoltine crosses the colour was not determined from the external appearance of the cocoons, but by extracting and estimating the colouring matter. It did not prove to be an intermediate character, but one with higher value than that of the paternal and maternal cocoons; these taking the total of the cases studied, attained 84 % of the sum of the parents' characters. Also in the present case this character was not intermediate; contrary to what occurred before, the average figure of all the observations was below that of the male bivoltines. On examining the phenomenon more in detail, the author found that when the annual breed produced males, the hybrid cocoons contained more colouring matter and when it produced females there was less colouring matter present.

To sum up. Whether bivoltine females were crossed with annual males, or bivoltine males with annual females was a matter of indifference as regards certain characters (size of cocoons, amount of fibrin in the raw silk), but not as regards others. In the first case, the two parents have the same effect upon the hybrids. In the second, either the sex of one of the parents exercised a special influence (weight of outer silk tending towards that of the females), or a new character has found its way into the offspring and dominated the opposite character, such as constriction in crosses between annual females and a bivoltine male, or else one breed imposed its character on the other, for instance, the length of the reelable silk has been increased by the bivoltine parent and the strength of the silk by the annual parent. In the case of elasticity, crossing on one occasion clearly shewed the determining factor conferring upon the character of the hybrids a higher value than that of the parents. Finally, a mixture of sex influence: the monovoltism and bivoltism of the two breeds crossed determined the special behaviour of the colouring matter. All these facts lead to the following modification of the schedule at the end of the preceding article.

#### A. — INTERMEDIATE CHARACTERS

##### a) *Attaining the average*

Size of cocoons.

Percentage of crude fibrin in the raw silk.

##### ax) *Sometimes attaining the average, sometimes inclining towards a special character in one of the parents, or one of the breeds:*

Shape.

Standard

b) *Deviating from the average :*

b<sub>1</sub>) *Below or above the average and tending towards a maternal character*  
Weight of outer silk

b<sub>2</sub>) *Below the average and inclining towards the breed, but with less pronounced character :*  
Length of reelable silk

b<sub>3</sub>) *Above the average and inclining towards the breed, but with more pronounced character :*  
Strength of thread

B. — NON INTERMEDIATE CHARACTERS.

a) *Superior to the characters of either of the parents*  
Elasticity of thread.

b) *Superior or inferior to the characters of the parents, and at the same time, associated with the monovoltinism or bivoltinism of the breeds crossed and with the determining sex*  
Colour

300 — **Connection between the Hour of Gathering of Mulberry Leaves and the Silk Yield of *Bombyx mori*.** — SACCHI, R. (Laboratorio di Bachicoltura del R. Istituto Superiore Agrario di Perugia), in *Le Stazioni sperimentali agrarie italiane*, Vol. I, IV, Parts 7-10, pp. 316-325. Modena, 1921.

In preceding experiments the author had found that silkworms fed on leaves picked in the evening instead of at day-break, produced a greater weight of cocoons per ounce of eggs and a larger quantity of silk on reeling (1). He has continued his studies and supplemented them by analytic researches on the chemical composition of mulberry leaves picked at sunrise and sunset, and gives the results in the report analysed.

The data obtained confirm the statement that feeding silkworms (yellow Ascoli) with mulberry leaves gathered at sunset rather than at dawn, increases the weight of the cocoons; in one experiment 3.225 kg. of cocoons per gm. of silkworm eggs was obtained as against 3.025 kg.; and in another 2.640 kg. as against 2 kg.) The cocoons were larger and more uniform, and the silk layer was thicker; 15.66 % as against 15.39 % in one experiment; 17.6 % as against 16.8 % in another. These cocoons also produced moths that laid a larger quantity of eggs; average weight of one laying 0.478 gm., as compared with 0.426 gm..

These results depend on the fact that leaves gathered at sunset are more nutritious than those picked earlier in the day, as they contain more sugar, starch, dextrin, fats and proteins. The larger the number of days of full sunshine during the rearing of the silkworms, the more advantage is derived from giving them mulberry leaves picked at the close of the day.

301 — **The Italian Sheep-Dog.** — MARCENARO, A. M., in *Bassa Corte*, Year II, Parts 47-48, pp. 965-986, Molassana (Genoa), December 1921.

VARIOUS  
ANIMALS

These are two varieties of sheep-dog in Italy; the Alpine and the Maremma.

The Alpine sheep-dog or "Cravino" of Bergamo greatly resembles in its general characters the French dog of la Brie, and performs the same services as the "bouvier" dog. It is a strongly-made, tall animal (about

(1) See *R. May* 1919, No. 629. (Ed.)

60 cm. in height), with thick neck, prominent withers, solid haunches, broad thorax and strong limbs; its coat is long and curly, and variable in colour: whitish, black with spots, hazel-brown, dead-leaf brown. It would be well to select the darkest, most intense and finest colour.

The Maremma or Abruzzi dogs belong to the same bred according to the author although more agile and lighter, owing to the adaptation to local conditions that is of general occurrence in all mountain breeds.

The Maremma sheep-dog is over 60 cm. in height (at the withers it is 65 cm.). Its coat is woolly, pure white and glossy. It has a well-developed frame, and strong body with shortish, strong legs; its feet are round and close, with very hard pads. As it has broad, strong haunches, it would make an excellent draught-animal, but is never so used.

Hitherto, the sheep-dog has not been systematically bred in Italy (except for private use) nor has it been the object of selection.

A "Circolo per i cani da pastore italiani" (Society for Breeding Italian Sheep-Dogs), has therefore been founded at Genoa under the auspices of the "R. Comizio agrario".

302 - **Breeding Fur-Bearing Animals in Canada in 1920** (1). — COATS, R. H. (Dominion Statistician), in *Canada Dominion Bureau of Statistics, Fur Branch*, 23 pp. Ottawa, 1921.

In 1920 there were 587 breeding establishments in Canada. Foxes were bred at 578 of these, martens at 6, muskrats at 2 and Karakul lambs at 1. In this list are included not only establishments solely devoted to breeding, but also farms where the raising of fur-producing animals is carried on at the same time as ordinary agricultural work. On December 31, 1920, the value of the fur animals in captivity was 4 722 905 dollars, most of this sum viz. 4 536 417 dollars being represented by the silver foxes.

The total value of fur animals sold by the breeders in 1920 was 763 221 dollars, of which 750 123 dollars were paid for silver foxes, 12 913 dollars for cross foxes and 185 dollars for other species. By estimating the average sale-price at each establishment it is found that the price of a silver fox varies between 100 and 1100 dollars. In 1920, 11 000 fur animals were born in captivity, 1618 died and 2322 were killed — the number of pelts sold during the same time was 2 470; the skins brought in 388 335 dollars; of this sum 373 140 dollars were paid for silver fox skins alone, each of which fetched from 75 to 750 dollars. At the end of 1920, the fur-breeding establishments were worth 5 925 496 dollars; the value of the land and buildings being estimated at 1 202 591 dollars, and of the animals in captivity at 4 722 905 dollars. The distribution of this industry in the various provinces is as follows as regards number of establishments: Prince Edward Island 309 — Nova Scotia 55 — Quebec 80 — New Brunswick 57 — Ontario 42 — Manitoba 2 — Saskatchewan 2 — Alberta 15 — British Columbia 11 — Yukon 14 — Total 587.

303 - **Horse-Chestnuts as a Food for Rabbits.** — LAMBERT, C., in *La Revue Avicole*, Year 32, No. 1, pp. 16-17. Paris, January 1, 1922.

The author found that the rabbits on his farm at Marville-les-Bois (Eure-et-Loire), would eat horse-chestnuts, provided the bitter principle was removed by boiling. The horse-chestnuts are passed through a root-cutter adjusted to give a light cut and they are then boiled in salt water and the resulting mass is crushed. This paste is fed sprinkled over with wheat bran. The horse-chestnuts are boiled every two days. This feed is supplemented with dry hay, broom and sliced beets.

The chestnuts have to be dried as soon as they are collected, so that they may be kept in heaps but at the same time free from damage by mould. Once this ration is fed it must be continued and not given in turn with any other food. F. D.

KAUL W., *Der Stand des Motorflugwesens*, *Ibidem*, No. 27, pp. 423-425.

AGRICULTURAL  
MACHINERY

I. — The author reports on the large number of agricultural machines and implements that have accumulated at the factories, and asks how this stock can be turned to account. Customers have been deterred from purchasing by the hope that prices will fall which however in his opinion, is not likely to occur.

He considers that about half the owners of mechanical cultivation machines are dissatisfied with them; this is due to the fact that the farmer does not understand his machine and the driver has not had the necessary mechanical training. Another cause of dissatisfaction is to be found in the poor quality of the oil. The owner also complains that he does not get the returns he expected, and that the engine is not sufficiently powerful. The author makes a comparative study of the apparatus for motor-cultivation, first contrasting the work of a plough with that of a mechanical rotary.

Among the machines using mould-boards for tilling the ground, he mentions the STOCK motor-plough, the HANSA-LLOYD tractor, the W. D. and the Ergomobil machines working on the same principle as the steam-plough.

The author also speaks of some of the latest tilling machines such as VOGELER's motor-plough, KOSTO's tractor with a single driving-wheel, the BENZ tractor, the FREUND motor-plough, the DEUTZ tractor, PODEUS's caterpillar tractors. The following machines also have new features: the BUSSARD motor-plough, the LANZ tractor, the EULM tractor, the VIVAG machine, the RICHTER tractor etc.

The manufacture of light tractors is a matter of great economic im-

portance; two have already been turned out; the RÜTGER tractor and the KÖRTING motor-plough.

The position of the mechanical cultivation industry is a very difficult one and is still further threatened by the possible introduction of American machines, especially the FORD tractor.

The only means of improving the situation would be an agreement between the manufacturers of machines of the same type.

II. — The author mentions the unsatisfactory results often obtained with mechanical cultivation. The chief cause of these failures is the lack of good drivers. In order to obtain well-trained men, it is necessary to offer them payment comparing favourably with town wages and to make them feel at home in the country by providing them with a comfortable house, a small plot of ground etc.

The author is very anxious that the German Agricultural Society should experiment in the mechanical tilling of the subsoil and in breaking up the stubble by means of flexible apparatus.

III. — The author describes the working of the HANSA LLOYD tractor, provided with a 25 H.P. engine, on his own estate of 350 hectares.

*Ploughing*: with 3 or 4-furrow ploughs, 2 to 3 hectares per 10 hour day.

*Breaking up stubble*: with 9-furrow-plough and a harrow, 4.5 to 7 hectares.

*Preliminary work in the spring*: 10 hectares per day. For ploughing the fuel consumption is estimated at 28 kg. per hectare, 1 ½ kg. of lubricating oil being used per day.

The saving effected by the use of a tractor is greater, the longer the machine is used. The author trusts that the working expenses will be reduced as soon as possible, but hopes this end will be attained by tractors constructed in the country such as LANG'S light tractor.

IV. — CLEVE-GRAUHOFF describes his own experiences with the STOCK motor-plough (old and new type), the VOGELER motor-plough, the HANSA-LLOYD tractor, and the FODEUS caterpillar tractor. He emphasizes the necessity for constructing light machines. G. B.

305 — **American and German Agricultural Machines.** — BILAU, K. in *Deutsche Landwirtschaftliche Presse*, No. 13, p. 88, Berlin, February 11, 1921.

In view of the possible introduction into Germany of light American tractors, the author examines the two following questions.

1) Would the introduction of a cheap light tractor be detrimental to the German mechanical industry?

The purchaser enquires before buying a plough, how much work it can accomplish, how long it will last and its net cost. Tractors are now the fashion whether this preference can be justified or not.

The fundamental difference between tractors of foreign construction and those made in Germany is that they are lighter and develop a lower H. P. At the English Meeting of 1919, 81.15 % of the tractors were

machines of between 20 and 30 H. P. The German tractors are both more powerful and heavier, as is shown by the Table appended to the article.

If powerful machines work more economically, it must not be forgotten that the German tractors are more expensive to buy.

A start has now been made in Germany with the manufacture of lighter tractors.

2. — In what way is it possible to protect German trade from this danger? In the first place by making lighter and also cheaper machines, with at the same time an increase in the return. G. B

306 — **The Construction and Use of Agricultural Tractors in Italy.** — I. IOPARDI, R., in *La Macchina nell' Agricoltura*, Year 1, No 10, pp. 6-8 Milan, December 1921

The author considers that one of the chief reasons why agricultural tractors are little used in Italy, is that all the machines on the market are of nearly the same power, the engine developing about 25 HP, and the attachment bolt 15 H P, whereas in the different districts and various conditions of agriculture in the country, the average motor power required is between 25 and 60 HP.

This mistake is due to the fact that the manufactures have been influenced by statistics of construction in the United States, where according to the data collected by the "Federazione italiana dei Consorzi agrari" of Piacenza (*Il problema della motocultura e la trattrice agricola Fiat*), 80 % of the tractors constructed develop 12 to 24 H P, 14 %, 24 to 40 H P, and 6 % over 40 H P. Too little attention has been paid to the fact that the soils of Italy differ very greatly in character from those of North America and that the plough therefore needs more traction force. In recent years also fewer 25 HP. types have been constructed in the United States, while a larger number of the more powerful tractors have been turned out.

In order to determine the minimum force required, it is necessary to take into consideration 1) economy of labour, 2) rapidity of work, 3) the average soil resistance

1) In practice one man is not sufficient to manage a tractor, two normally being required in order to save undue loss of time in the event of unavoidable accidents. The two men in charge of a tractor receive the same wages as three peasants doing the same work with a team of animals. The saving of labour thus begins in the case of a tractor from the moment it can draw a two-share or three-share-plough for deep ploughing, or a four-share or five-share-plough for superficial cultivation.

2) In order to do the work at the right time, it must be possible to execute it quickly; the most useful speed for tractors is reckoned at 3.6 km. per hour.

3) From experiments carried out in Italy (at Melegnano, Lodi, etc.), the following data have been obtained as regards soil resistance: in deep ploughing, from 60 to 70 kg. per sq. dm. of the cut; in superficial ploughing from 40 to 50 kg. per sq. dm. From these data it is possible

to calculate the minimum force required from a tractor for the various cultural operations.

Allowing for: a speed of 3.6 km. per hour (1 metre per second), a depth of 70 cm. for deep ploughing and 20 cm. in the case of superficial ploughing and a cut 30 cm. in width for each share, we should have the following cases:

A. -- For deep ploughing:

a) with one-share tractor: cutting 9 sq. dm.; power necessary at attachment bolt  $9 \times 70 \times 1 = 630$  kilogram-seconds.

b) with 2 share tractor: cutting 18 sq. dm.; power necessary at attachment bolt  $18 \times 70 \times 1 = 1260$  kgm-sec.

c) with 3 share tractor: cutting 27 sq. dm.; power necessary at attachment bolt = 1890 kgm-sec.

B. -- For superficial ploughing: d) with 2 share tractor: cutting 18 sq. dm.; power necessary at attachment bolt  $18 \times 50 \times 1 = 900$  kgm-sec.

e) with 4 share tractor: cutting 24 sq. dm.; power necessary at attachment bolt  $24 \times 50 \times 1 = 1200$  kgm-sec.

f) with 5 share tractor 30 sq. dm. power necessary at attachment bolt  $30 \times 50 \times 1 = 1500$  kgm-sec.

It is necessary to provide a little extra power to meet unexpected increases in resistance. If these are allowed for by increasing by  $\frac{1}{4}$  the powers given above, the figures become respectively: 790 — 1580 — 2370 — 1125 — 1500 — 1875 kgm-sec.

With the best types of ordinary tractors, the average output would hardly exceed 50 %. Hence the engines generating the above-named powers should develop:

a) 1500 kgm-sec. or 21 HP

b) 3160 " " " 2 "

c) 7170 " " " 63 "

d) 2250 kgm-sec. or 30 HP

e) 3000 " " " 40 "

f) 3750 " " " 50 "

If to avoid a too heavy machine a one-share tractor only is used, it is at once seen, from what has already been said, that there ought to be at least 3 types of tractor on the market, of respectively: 15 to 25 H P; 17 to 35 H P; 22 to 45 H P.

The necessity of having at least these 3 types in order to satisfy the demand and requirements of different farmers depends on the fact that these tractors are also used for another important purpose, viz., to work the threshing-machines often coupled with forage presses. In order to work these machines the following powers are necessary:

0.75 Thresher with Press 15-18 HP.

0.61 " " " 18-20 "

1.07 " " " 23-25 "

1.22 " " " 26-30 "

1.37 " " " 30-36 "

Ploughing to a depth of 40-45 cm., could always be done with a one-share tractor without giving up all the advantages afforded by an agricultural tractor.

work.

machines by means of a belt.

(1) See R. Oct.-Dec. 1919, No. 1222 I. p. 1273. R. March 1920, No. 354. (*Ld*)

with slanting protections ; they work conjointly with the axle or separately and independently of it, acting on handles attached to the centre of each wheel which uncouple the tractor, or cause it to go forwards or backwards by adjustments in the pawl-boxes of the nave. There is no speed-gear, and the turning radius is very small the turning being carried out on one wheel.

To this fore-carriage are attached various agricultural machines provided with a seat from which the driver can work the unrevolvable steering-wheel at the side of which are two handles one for the carburettor, and the other for uncoupling.

Fore carriage Tractor « Agro » attached to a reaper

The total weight of the fore-carriage tractor is about 850 kg, its external width of 1.08 m allows it to be used in vineyards, especially as it can turn on a very small radius.

To the fore carriage can be attached, according to the work to be done, a one two or three furrow two way plough. The attachment of a single two-way plough for harrow ploughing is an easy matter.

To the back of the fore-carriage is affixed an attachment system for different agricultural machines. In the case of reapers or harvester-binders, the pole is replaced by a very short beam of which the front portion is shod with iron.

The working speed varies from 3000 to 4500 m per hour. According to information supplied, the following work could be done per hour.

ploughing to a depth of 0.25 m. : 10 *ares* — ordinary ploughing from 0.18 m. to 0.20 m. : 15 *ares* — breaking up stubble from 0.10 m. to 0.12 m. : 25 *ares* — with cultivator with flexible teeth : 30-50 *ares* — reaper and harvester-binder : 35-40 *ares*.

The hourly consumption of fuel would vary with the character of the work from 2.5 to 3 litres of petrol to which must be added 5 to 6 % of lubricating oil.

Several machines can be belt-driven even if the engine is left on its frame in the fore-carriage tractor, but it can easily be detached being kept in place by 4 bolts only, and put in any required position, it in communication with a supply of petrol.

G. B.

309 - **Power of the Engines of Tractors.** — PASSALEGUE, G., in *Journal d'Agriculture pratique*, Vol. 36, No 36, pp 212-214 Paris, September 12, 1921

The numerous tests made of the engines of tractors at the Paris Machine Trial Station show that the maximum power obtained at the pulley is only  $\frac{8}{10}$  of the force developed by the machine at the test-bench. Therefore, before purchasing a tractor it is well to consider its actual hauling power rather than the engine's record at the testing Station.

G. B.

310 - **Wedging a Tractor.** — RINGELMANN, M., in *Journal d'Agriculture pratique*, Vol. 1, No 12, pp 234-236 Paris, March 16, 1921

The author mentions several ways of wedging a tractor working as a stationary machine. Of these the following method adopted in America is the most interesting. A piece of wood is applied to the outside of the tires of the wheels on either side. The wood is placed obliquely against the wheel of the largest diameter, it skirts the second wheel, and is buttressed on the ground. The beam is affixed to the tires by means of braces.

G. B.

311 - **Rear-driven Tractors.** — RINGELMANN, M., in *Journal d'Agriculture pratique*, Vol 1, No 14, pp 275-276 Paris, April 9, 1921.

The author states the conditions to be fulfilled by a tractor in order that it may be driven from the rear, that is to say, from a seat on the machine towed by the tractor.

- 1) The engine must be provided with an automatic speed regulator.
- 2) Coupling and uncoupling must be effected by a rope if required.
- 3) It must be possible to prolong the steering shaft backwards.

G. B.

312 - **A Charcoal Gas-Engine for Tractors** (1). — GREILSAMMER, in *Journal d'Agriculture pratique*, Year 85, No 41, pp 318-319, 1 fig Paris, October 15, 1921

In the course of a public demonstration of Mechanical Cultivation given by the Association of Stockbreeders and Agriculturists of Indre,

(1) See *R* Jan 1922, No 95 Other experiments with tractors running on poor gas and burning charcoal have been carried out by the Agricultural Co-operative Society of Berry (Department of Indre). The tractor, provided with a gas-engine, towed a 3-furrow plough

on September 23 and 24, 1921, the CAZES gas-engine, type D L, was tested at Châteauroux. This engine, which developed 30 to 40 HP, was mounted on a TOURAND-LATIL tractor with a 35 HP, 4 cylinder, petrol engine (of 0.105 m. bore, and 0.140 m. stroke at 1200 revolutions per minute).

The gas-engine and purifying apparatus are mounted on a platform at the back of the tractor.

The gas-engine consists of a sheet-iron cylinder with a non-conducting lining and a bottom without a grating having an opening in its circumference through which the steam is admitted. The boiler producing the steam is situated in the upper part and works on the principle of immediate steam generation, independently of the slope of the ground. The water feeding the apparatus flows through and falls drop by drop from a small copper pipe upon a grating pierced with holes that covers the boiler.

The steam thus produced passes through a cooler at the side of the gas-engine where it cools the heated gases that are travelling in the reverse direction. Then the steam at once finds its way to the bottom of the gas-engine.

The gases after passing through the cooler go through the scrubber, which is formed of a column of coke.

A fine rain falls upon the coke from a spiral cooler in the upper part of the scrubber which is supplied with water from the tank above.

On leaving the scrubber, the cooled and purified gases pass into a chamber where they come into contact with a number of U-shaped vertical pieces of iron upon which they condense, depositing droplets of water and small particles of tar. The gases are then conducted into a box containing horse-hair, wadding or other absorbent material, where they are finally purified and freed from the last particles of tar. Thence the gases pass into a mixer acting as a carburettor, where the required amount of air is added.

This mixer consists of a cylindrical chamber with an opening of varying size which is regulated by the displacement of a circular jacket. The air is drawn in through this aperture and mixes with the gas entering through a throttle-valve by which its flow is regulated.

The amount of gas and of air is controlled by two regulators worked by handles placed near the hand of the driver. This mixer, which is of very simple construction, works admirably and is less delicate than an ordinary carburettor.

The whole plant is completed by a ventilator worked by a handle (supplying the gas-engine with the air required for combustion and ignition), and by a funnel placed before the cooler and above the exit-pipe for the gases coming from the gas-engine.

on heavy soil Depth of ploughing 15 cm consumption per hectare. charcoal 45 kg water 50 litres. As the charcoal was bought at 0.22 fr per kg. the cost of the fuel used was 9.90 fr. per hectare — G. PASSELEGUE, "Tracteurs à gaz pauvre", in *Journal d'Agriculture pratique*, Vol. 36, No 39, p. 279. Paris, Oct. 1, 1921. (Ed.)

A tank with a capacity of 80-100 litres distributes the water to the scrubber and the gas-engine by means of regulating tap.

The gas-engine with its accessories takes up comparatively little space, the whole apparatus is about 1.55 m. high, 1.50 m. wide and 0.50 m. long; thus its volume is not much over 1 cubic metre.

The total weight of these engines is about 500 kg., and could be reduced to 400 kg. by decreasing the weight of the fire-proof clay lining.

The size of the CAZES gas-engine allows it to be used for all existing tractors, but it would have to be considerably reduced to adapt it for machines of about 20 HP.

The author's statements may be summarised as follows.

The maximum consumption, when ploughing with a 3-furrow plough to a depth of 0.15 m. and a breadth of 1.05 m., is 52 kg. of charcoal and 62 litres of water per hectare.

Another tractor, the TOURAND-LATHI, which is identical but runs on petrol, drew a 4-furrow plough on the same day at the same speed, which would seem to show that the maximum loss of power in substituting poor gas for petrol would be 25 %.

Charcoal bought retail at 0.22 fr. the kg. in Châteauroux cost 11.45 fr. per hectare, as against 72 fr. paid for petrol. This represents a saving of 60 fr. per hectare, or 85 % on the fuel expenditure. F. D.

313 - **On Accidents due to Tractors.** — RINGELMANN, M., in *Journal d'Agriculture pratique*, Vol. 36, No. 29, pp. 71-73 Paris, July 23, 1921.

The author investigates the various accidents that have occurred, and advises in order to guard against mischance that the driver should tape his seat upon the machine in tow and not upon the tractor.

G. B.

314 - **The "Buckeye" Tractor Ditcher for Land Drainage. Trials in England.** — GARNER, H. V. (School of Agriculture, Cambridge), in *The Journal of the Ministry of Agriculture*, Vol. XXVII, No. 1, pp. 306-320, Tables IV, figs. 2. London, July 1921.

Report of trials with this American machine conducted at Croxton, Cambridgeshire (England), following on highly successful results in Scotland.

The "Buckeye" tractor ditcher here described is designed on the rotating wheel system and the following is an abridged specification: 20 h. p. 4-cylinder petrol engine; digging wheel 11 ½ in. or 14 ½ in. wide × 4 ½ ft. deep, or 11 ½ in. wide × 5 ½ ft. deep; length over all 25 ft.; width over wheels 8 ft. 6 in.; extreme height 8 ft. 9 in.; digging speeds 2 ½ ft. to 9 ft. per minute; road speeds 1 to 1 ½ miles per hour; approximate shipping weight 7-9 tons; width of front wheels 10 in.; width of extension tyres to front wheels 8 in.; width of caterpillar track, 22 in., centre of ditch to centre of spoil bank 4 ft. 3 in.

The chief points of the machine are as follows:— Substantial main frame and platform constructed of steel T-beams connected at intervals by crossbeams and strongly reinforced, carries at one end a 20 h. p. en-

gine unit and transmission system, and at the other the cutting wheel hinged to the platform. The frame and superstructure are supported at both ends on 3-point suspension trucks which eliminate severe twisting strains.

The digging wheel is mounted midway between the two main girders and is held in a 3-point suspension frame hinged to the main platform. Power is transmitted to the wheel by a system of chains running on sprocket wheels ; by shifting a high speed chain from one set of a series of graduated sprockets to another, 4 digging speeds ranging from 2 ½ ft. to 9 ft. per minute can be obtained. This plan is found to be very satisfactory and effective.

A feature of the transmission system is a safety device in the form of a friction cone clutch, which slips when the machine strikes an obstruction beyond its capacity, thus averting a breakdown. On the outside

FIG. 1. — « Buckeye » Tractor. Ditcher at rest.

rim of the digging wheel are mounted buckets of deep section which can be suitably equipped for varying classes of work.

Adjustment of the depth of the digging wheel is obtained by a hoist worked from the engine and operated through a double boom, the cables communicating with both the front and the rear of the wheel frame. If the wheel is rotated and lowered, keeping the forward end of the frame some 3 ft. lower than its rear end, the buckets will dig themselves into the ground at this angle as the whole machine is advanced. At some pre-arranged depth, the descent is checked by means of the front cables ; the rear cables are then slackened, allowing the curved sole which follows the digging wheel to take the weight of the rear of the wheel and thus mould and smooth the floor of the trench.

The method of adjustment in order to obtain a drain of even fall when the machine passes over uneven land is described in detail. Follow-

ing in the appended diagram, A B C represents an irregular surface below which the drain has to be cut. At intervals of about 50yds. along this line, levels are taken in the usual way. Having decided the fall required in the drain, the depths below the surface at which the floor of the trench must lie at A, B and C are calculated. (Suppose these depths are 4 ft. 6 in., 3 ft. and 4 ft. respectively, as in the diagram where F G

FIG. 2. — Buckeye Tractor. Ditcher at work, Back view.

represents the bottom of the drain and F H the horizontal). The movable cross members A X, B Y and C Z are adjusted in correlation with a horizontal sighting rod D fixed to the frame of the digging wheel E of the ditcher. If D is fixed 9 ft. above the level above the floor of the drain, A X, B Y and C Z must also be fixed at 9 ft. above the level at which the drain is to be dug; thus A X at point A will be 4 ft. 6 in. above ground, and B Y will measure 6 ft. above ground at B etc. The machine

is then moved to the outlet end A of the drain, since digging always proceeds uphill, and made to face along the line of standards. The digging wheel is made to cut its way into the ground; when the rod D intersects the line of cross-members, the further descent of the wheel is stopped by the winding gear. The ditcher now proceeds along the line of the proposed drain and it is important to keep the rod D constantly in alignment with the cross-members by raising or lowering the wheel E in accordance with the irregularities of the land. If this is done carefully, a trench with an even fall can be excavated in a single operation.

In describing the methods to be adopted in dealing with this machine, it is noted that two men are sufficient for the actual working. Arrangements should be made to lay the drainage pipes close behind the machine, as delay in doing so will probably result in loose earth falling into the finished excavation.

FIG 3 — Diagram shewing the method used to regulate the depth of the trench when the Ditcher passes over uneven ground.

The trials were carried out on 2 types of demonstration field:—

1) a 12-acre bare fallow of gentle and uniform slope; about 5 in. of dry friable soil on the surface with moist and sticky clay below. In the upper parts of the field, bands of chalky gravel were found in the clay.

2) wheat stubbles with hard-baked clay surfaces resting on dry clay. (The mechanical analyses of the respective subsoils is shown in tabular form).

It was subsequently found that the ditcher could operate more rapidly at any given depth in a dry clay subsoil containing chalk and gravel than in a wet clay subsoil. The machine proved itself capable of excavating straight trenches for land drainage to any depth not exceeding 4 ft 6 in. but difficulty was found in excavating trenches with a curve approximating to a right angle and under such conditions, it is considered advisable to build a catchpit at the angle of the bend.

The rate of excavation measured in chains per hour obviously increases rapidly as the trench becomes shallower, the type of soil being

the same ; the speeds vary according to depth and moisture of subsoil ; 3 ft. 6 in. drains in moist clay were dug at the rate of 1.7 chains per running hour, and in dry clay at 3.0 chains per hour ; 2 ft. drains in dry clay at 9 chains per hour. The rate of fuel consumption is roughly constant at all speeds varying from 2-2.8 gall. per hour. (The machine is fitted with an automatic cut-out, which acts like a governor and causes the engine to run at constant speed). Indications are also given showing how much work could be done under the various conditions of depth and soil if it were kept running *e. g.* for 7 hours per day. Under these conditions about 63 chains of 2 ft. minors could be dug in dry clay, 21 chains of 3 ft. 6 in. mains in similar clay or 12 chains of 3 ft. 6 in. mains in wet clay.

An attempt has been made on a conservative basis to estimate the costs of operating under commercial conditions, and they compare favourably with present costs of hand digging ; the calculation is shown as follows :—

2ft. 6in. branches	in moist stiff clay where 1.7 chains were excavated per hour				
	cost 20s. 11d. per chain				
2ft. 6in. "	similar clay	cost	10s. 2d	per chain	
3ft. 7in. "	dry clay	"	11s. 11d	"	"
2ft. 9in. "	dry clay	"	7s. 9d	"	"
2ft. "	dry clay	"	4s. 0d	"	"

It is noted that hand drainage is done at an average rate of 2 chains of 2 ft. 6 in trench per day of 8 hours compared with Buckeye drainage in about 20 minutes.

The trial showed that the friction produced by the revolution of the digging wheel in moist clay greatly retarded the speed of work and raised the cost, but by fixing scrapers to the framework and adjusting them to remove the adherent clay from the sides of the wheel, much of the friction could be obviated. By fitting the drainer with a wheel and buckets capable of digging trenches 11 in. as a maximum and 8 in. as a minimum, instead of 14 ½ in. maximum and 11 ½ in. minimum, considerable economy of cost of operating might be expected.

The machine is not suitable for purchase by farmers unless operating on a very large scale ; it is suitable for use by agricultural contractors or by landowners with large estates.

M. L. Y.

315 - **Motor-Plough for Ploughing on the Flat.** — DESSAISAIK, R., in *Journal d'Agriculture pratique*, Vol. 36, No. 38, p. 253. Paris, September 24, 1921.

Description of the Tournesol disk-plough with reverse or shuttle-action.

This machine consists of a central portion including the engine with its accessories, as well as the driving-wheels, and of two symmetrical parts placed at each end, one of which works only when the machine is reversed and the parts of the other are removed from the soil. At the end of each furrow, the function of each working portion is reversed.

The central part includes the engine which sets in motion 3 driving-wheels, one on the side of the furrow, and two land-wheels, of slightly smaller diameter. These two wheels or one of them (the other remaining fixed) can be slanted by the steering-handles, which are each worked from one of the two seats successively occupied by the driver.

Tournesol Motor Plough: back view

The engine is said to develop 30 HP ; it makes 1100 revolutions a minute, and has 4 vertical cylinders of 0 100 m. bore. The pistons have a stroke of 0 160 m. In continuous work this engine can develop 37.16 HP. It has two speeds ; one of about 2500 and the other of about 4 000 m. per hour. Total weight of motor-plough : about 4 000 kg.

In the model represented in the figure, the working parts consist of mould-boards with disks mounted on either side on two frames that are raised at the end of the furrow by coupling the engine on a slanting tube acting as a windlass, around which are rolled the elevating cables. If the soil is very heavy and the ploughing deep, 3 disks may be used in place of 6.

Manufactured by : Société Delahaye, 10 Rue du Banquier, Paris.  
G. B.

316 - **New Machine with Flexible Teeth and Rotating Forks.** — *Deutsche Landwirtschaftliche Presse*, No. 5, p. 33, Berlin, Jan. 19, 1921.

The manufacturer having noticed that experiments in loosening the soil have proved that it is not always necessary to turn over the earth as is usually done, has devised a new apparatus of which figures are given. It consists of a frame upon which are mounted the flexible teeth of a cultivator. These make a series of furrows, the loosening of the soil being subsequently effected by a system of forks similar to those attached to a potato-digger.

G. B.

317 - **Choice of Machines based on Spring Awakening of Arable Land.** — See No. 235 of this Review.

318 - **Pantzier Machine for Chopping and Distributing Manure.** — *Deutsche Landw. Presse*, No. 15, p. 100, Berlin, February 25, 1921.

This apparatus consists of a hopper in the form of a barrel mounted on 4 wheels. The interior of the hopper is covered with blades between

which pass other blades attached to a shaft, the movement of these blades setting the wheels in motion. On leaving the hopper, the manure passes into a funnel fitted with other blades that complete the work. It is distributed by means of a horizontal disk with a rapid rotary motion. G. B.

319 - **The Decortication of Beet Seed.** — RINGELMANN, M., in *Journal d'Agriculture pratique*, Vol. 1, No. 11, pp. 214-216. Paris, March 19, 1921.

The author discusses the advantages derived from decorticating beet-root seeds in such a manner as to set free the seeds contained in the glomeres, and describes the mechanical means to be adopted for the purpose.

As a result of experiments in hulling the different varieties of rice from Central Africa, Madagascar and Indo-China, he was led to try the same machines for the decortication of certain seeds (those of the beet, sainfoin, sulla and carrot) which are difficult to sow or reluctant to germinate. He found that the small model of the Neptune crusher (Messrs. PILTER, Nevers), when properly regulated to 38 revolutions per minute, decorticated 5 kg. of Tunisian sulla and 6 kg. of Egyptian sulla per hour, these seeds being much harder to hull than carrot or beet seeds.

Another trial was made with the "Melchior" rice huller of the General Millstone-Makers' Society of Ferté-sous-Jouarre, Seine-et-Marne. The working part of the machine consists of a truncated cone with a vertical axis, the whole surface being covered with perforated sheet-iron. The fly-wheel fitted inside with 147 teeth, engages with a pinion of 27 teeth mounted on a small horizontal axis having at the end two angle wheels, which set in motion the vertical axis of the truncated cone (the decorticator). With a speed of 38 revolutions of the fly-wheel, 18 kg. of Tunisian sulla seed and 15 kg. of Egyptian sulla seed are decorticated per hour.

With these two machines from 7000 to 7300 kilogrammetres are needed for decorticating 1 kg. of sulla. G. B.

320 - **Haupt Potato-Planter with Cylindrical Hopper.** — *Deutsche Landwirtschaftliche Presse*, No. 11, p. 75, Berlin, February 9, 1921.

The drum containing the tubers for planting has on its circumference 8 openings corresponding to pointed funnels. The funnels when they come to the upper part of the cylinder, fall inwards from their own weight, and receive the potato. When they reach the bottom however they leave the drum, and the potato falls into the furrow. G. B.

321 - **Motor-Mowers.** — PASSELEGUE, G., in *Journal d'Agriculture pratique*, Vol. 35, No. 2, pp. 31-36. Paris, January 13, 1921.

The author gives a description of the VALLOTTON and the FORD types of motor-mowers and refers to the results obtained in 1914 by RINGELMANN with the VALLOTTON mower.

Nature of Field	One year old Lucerne	Natural meadow
Average width of swathe. . . . .	1.04 m.	1.14 m.
Time taken to mow 1 hectare . . . . .	4 hrs 30 min.	3 hrs 15 min.
Petrol consumed per hectare . . . . .	4.85 kg.	4.56 kg.

322 - **Reaper-Binder for Tractor.** — RINGELMANN, M., in *Journal d'Agriculture pratique*, Vol. 36, No. 27, pp. 32-35. Paris, July 9, 1921.

The author discusses the question of the preliminary circuit of the field, and with the AVELING and PORTER steam-reaper which renders the operation unnecessary in mind, suggests that a tractor could be attached to the reaper-binder.

In this reaper, which was shown at the Universal Exhibition at Paris in 1878), the engine carried the jib of a crane *a* (see appended figure), and a windlass that could be coupled when required with the engine *n*; in front was a reaper, *M*., supported by the crane *a* which allowed the height of the stroke to be regulated. The reaper and the crane were connected with the engine *A* by two shafts *b* whose rotation axis *x* coincided with the transmission axis worked by a GALL chain. At the end of the machine, when it was necessary to turn, the mechanic raised the reaper *M* by engaging the windlass of the crane *a*.

The AVELING and PORTER Reaper-binder.

The AVELING and PORTER mounting with the crane jib and windlass can be used with advantage if a reaper-binder of the present type is attached to the fore-end of a tractor. The movement would be transmitted from the engine to the different parts of the reaper-binder by means of chains. G. B.

323 - **Stooker for Large Threshing-Machine.** — SOURISSEAU, V. H., in *Journal d'Agriculture pratique*, Vol. 25, No. 16, pp. 311-316. Paris, April 23, 1921

This elevator (constructed by the Society of the "Olive" Stookers, 32, Rue de Metz, Toulouse), works like a straw-stacker. It consists mainly of a carrier with chains mounted on the thresher.

The frame supporting the platform of the elevator is enabled, by means of a handwinch, to rise to the top of the rick and follow its level progressively as far as the ground.

The apparatus turns round a vertical axis and it can be pushed into any given position, so as to take sheaves on the right or left of the threshers. For purposes of transport the apparatus can be folded and arranged on the platform in such a manner as to take up less room. It is possible to combine the elevator with an automatic hopper.

Fig. 1. — Elevator with automatic hopper, side view.

Fig. 2. — Stooker, end view.

Fig. 3. — Stooker, plan.

**TRANSMISSION OF THE MOVEMENT TO THE PLATFORM.** — The platform is formed of two ledges fixed on two chains with detachable links passing over two cog-wheels, placed at either end of a wooden frame in the form of a ladder which is articulated with the shaft *AA* (figs. 1, 2 and 3). This shaft which transmits the motion to the platform is supported by a frame articulated at *BB*. This frame is kept vertical by the detachable props *KK'*. The shaft *AA* is governed by the transmission *AC*, *CC'*, *XY*, *EE'*, *FF'*. In order to catch the sheaves, the ledges are provided with points

*P*, kept in the position shown in the figure by means of an erg sliding into a groove at *U*. On the right of the shaft *AA*, the erg leaves the groove in *U*, its points become loose, and the sheaf falls into the cradle. Then the worker cuts the rope and throws the sheaf into the threshing machine, or automatic thresher.

A coupling device with claws is affixed to the shaft *CC'*. A pedal *P* which the worker can depress with his foot disengages it instantly.

**RAISING AND LOWERING THE PLATFORM.** — The frame supporting the platform is articulated with *AA*, it rests on a roller *R* which is kept in place by a system of pivoted levers *NI*, *IQ*, *QR*. The levers *IQ* and *QR* are connected by a chain *UV* with a swack-absorber hook and spring. The system *IQR* articulated with *I* rests on the erg, *J*.

A steel cable rolled on the drum *T* of a winch which is fixed on the vertical shaft *AB*, allows the platform carrying the sheaves to be raised or lowered with the raising or depressing of the lever *NJ* about the pivot *N*. A protecting hoop is fixed at the end of the trough.

**ORIENTATION OF THE APPARATUS.** — The elevator is mounted on a kind of turning-plate resting on a rail *r* (fig. 3) and turning about the axis *XY*. In whatever direction the apparatus is turned, the motion is transmitted by conical pinions.

**FOLDING THE APPARATUS FOR TRANSPORT OF THE THRESHER AND SETTING FOR WORK.** — The operations to be performed are as follows. Turn the apparatus through 180° from the position it occupies in fig. 1. Lower the platform until the two uprights of the frame rest on the supporting roller *S*, fixed at the end of the thresher. Raise the roller *R*. The steel cable *t* being no longer stretched is unhooked and the lever *QR* folded back on the lever *QI*. The vertical frame *AB*, is folded forward after unpinning the props at *K'*. The apparatus now rests on the turning-plate and the rail, the stacker being on the top. The machine is set up by reversing the above operations.

**TESTS.** — The author has tested this elevator upon a large threshing-machine with a beater 1.22 m. long and a platform 4.80 m. from the ground. The frame carrying the platform of the elevator measured 4.80 m.; the end of the frame could sink to the level of the ground, and rise to a height of 5.70 m.

The transmissions were arranged so as to make the platform travel 0.70 m. per second. The output has been estimated several times at 30 sheaves per minute. When working normally the machine uses on an average  $\frac{1}{2}$  HP.

G. B.

324 — **The Laskowski Apparatus for Preventing Accidents during Threshing.** — *Deutsche Landwirt. Presse*, No. 15, p. 106, Berlin, February 25, 1921.

This apparatus consists of a metal frame of suitable height separating the thresher from the feeding-hopper; a grating protects him from falling grain.

G. B.

325 - **Carrying the Harvest on a Light Road Tractor.** — LIERMAN, M., in *Journal d'Agriculture pratique*, Vol. 36, No. 52, pp. 528-529. Paris, December 31, 1921.

The author gives the results obtained in transporting the harvest 1 km. by means of a light tractor towing 4 trucks which saves 20 % of the cost of using horses and carts. A saving of perhaps 40 % might be effected if 5 trucks were employed and the transport distance were limited to 1 km. or less. G. B.

326 - **The Guidetti and Piazza Cellar Presses.** — CASTELLI U., in *La Macchina nell'Agricoltura*, Year 1, No. 10, pp. 9-11, figs. 4, Milan, December 1921.

The author describes two types of cellar presses of Italian manufacture which were commended at the "Esposizioni Romane riunite" held at Forlì towards the end of 1921.

Messrs GUIDETTI and Co. of Reggio Emilia make several kinds of hydraulic cellar presses with hand-pump.

The "GUIMOR" type shown in fig. 1 has 2 cylinders with a conical axis; the larger cylinder which is under the basin, exerting the pressure and the smaller carrying out the return movement, both motions being produced by the help of a single hand-pump with two concentric pistons (for high and low pressure) and an intermediate tap with 3 screws.

This press is made in 4 sizes with a capacity of 400-500-668-808 litres respectively, the diameter of the basin being 0.80-0.90-1.00-1.10 m. and its height 0.80-0.80-0.85-0.85 m. The pressure exerted in order to obtain in the cage a pressure of about 9 kg. per sq. cm., varies from 170 to 250 atmospheres, or nearly double the pressure obtained with presses furnished with ordinary screws, in which case the ratio between the diameter of the screw and that of the cage would be 1 : 10.

Another press made by the same firm, the "B type", has one pressure cylinder, the cage and plate slide on a frame that rises against a fixed socket placed above it and supported by architraves and 2 columns, which is an arrangement similar to that customary in ordinary oil-presses. The return movement is produced by the weight of the movable part. Dimensions: diameter 1 m.; height of cage 0.85 m.; capacity 668 litres; pressure 12 kg. per sq. cm., works under a pressure of 285 atmospheres.

The same Firm also makes presses with 2 or 4 rolling vats or reving vats.

Figure 2 shows the "Torchio continuo per mosti e vinacce" or continuous press for musts and pomace, of PIAZZA Bros. of Ravenna. In these vats pressure is applied by means of a single screw with horizontal axis, turning in a cylindrical cage and pushing forward the pomace that has been exhausted in the upper hopper, driving it towards the exit where the opening of the cage is circumscribed by a conical stopper provided with a pressurespring that can be regulated. The push and counter-push being transmitted to the axis of the screw, neutralise one another. A special contrivance prevents the contents being carried along by the rotatory motion. The machine is completed by apparatus for feeding, and transmission by fixed or free pulleys and if necessary by a frame and rammer. It can press 60 quintals of grapes in an hour.

327 - **On the Choice of a Pump.** — RINGELMANN, M., in *Journal d'Agriculture pratique*, Vol. 36, No. 30, p. 91. Paris, July 30, 1921

The author after calculating the water requirements of an agricultural farm during the various seasons of the year, describes the different engines that can be used to work the pumps.

For every plant this choice depends upon the type of engine, the water raised per second, and the total height to which the water has to be raised. Of the pumps that fulfil the required conditions, the one that works best and costs least for installation and maintenance should be chosen. The mechanical output, although important, ought not to play a preponderant part in deciding the choice of a pump.

G. B.

328 - **A Deep Suction Pump.** — *Deutsche Landwirtschaftliche Presse*, No. 1, pp. 34. Berlin, January 5, 1921

With this special type of pump the usual depth of suction, which is practically 6 to 7 m., is raised to over 20 m. The pumping-engines are installed on the surface of the ground and the deep suction apparatus is sunk below the water-table

G. B.

329 - **The Work of Teams** (1). — RINGELMANN, M., Travail utilisable des attelages, in *Journal d'Agriculture pratique*, Vol. 36, No. 47, p. 420. Paris, November 26, 1921 — II IDEM, Prix de revient de la journée de travail d'un cheval. *Ibidem*, No. 48, p. 451. December 3, 1921. — III IDEM, Travail utilisé des attelages, *Ibidem*, No. 49, pp. 472-473. December 10, 1921. — IV IDEM, Repartition du travail des attelages, *Ibidem*, No. 52, pp. 529-531. December 31, 1921

I. — It has been found that under normal conditions the field-work of teams lasts at least 3 hours less than the time intervening between sunrise and sunset. The author gives a graphic curve showing the actual monthly work of ploughing-teams, using as his basis the astronomical and meteorological data available.

II — Taking into account the feeding, annual depreciation, shoeing, harness, interest on capital outlay and veterinary expenses, the author, basing his calculation on 275 work-days, reckons the cost of the team at 16.55 fr. per day without counting the expense of the driver.

III — The author, basing his statements on notes taken in 1911, 1912, and 1913, at a farm in the South-west of the Department of Oise, divides the work of draught animals under its different heads. In the 2 busiest months (March and October) out of 100 working days, 32.5 and 28.1 are respectively devoted to ploughing, and 30.6 and 47 to carting.

Further the number of days when the animals are actually used, is less than the possible number; there being as a rule a deficit of 30 % charged on the general farming expenses.

IV. — The author continues his examination of these data. He shows that for various reasons it is impossible to turn to full account the draught animals on a farm, and determines for the case considered, the number which are unused most of the time and could with advantage be replaced by mechanical motor power.

## AGRICULTURAL INDUSTRIES

331 - **Investigations on Potato Storage during the Hot Season in Western India.** — MANN, H. H., and NAGPURKAR, S. D., in *Investigations on Potato Cultivation in Western India*, Bulletin No. 102 (of 1920), Department of Agriculture, Bombay, 1921.

STORAGE  
OF CROPS

The "heat rot" or "black heart" of potato has led to loss of germinating power and rendered potatoes useless for seed to a very large extent in Western India. The elimination of this form of rot in stored potatoes is a matter of serious importance at the present time. The authors here describe the best systems so far adopted.

Apart from actual diseases present in tubers, there appears to be no risk in storing at any temperature below 86° F and little danger below 90° F provided that there is sufficient aeration among the stored tubers. The period of danger is between early March and the end of May, or later when the monsoon rains are delayed. During this period the following method has proved distinctly advantageous: —

A shallow pit (usually 10 ft. long, 5 ft. wide and 18 in. deep) is dug under the shade of a tree or under a roof; this is filled with water which is allowed to soak away and the space to dry for 5 days.

The sorted potatoes are then heaped upon it, generally to a depth of 3 to 3 ½ ft. but sometimes as deep as 4 to 5 ft. and covered with a thick layer of grass or broad leaves. The temperature is kept down by occasionally filling a ditch dug round the pit with water and sprinkling the heap of potatoes. In such heaps the temperature has risen to 92 or 93° F but no higher. If the shade is considerable, the temperature does not rise to the same extent and in some cases has not exceeded 86° F.

Other cultivators have stored potatoes in substantially built store houses, usually in heaps from 2-3 ft. thick, and seed potatoes are turned and sorted frequently. The temperature in these heaps varied from 86 to 93° F.

It is considered likely that when the process of fumigation of potatoes becomes general and it is possible to reduce the damage done by the potato moth (*Phthorimea operculella*), these two methods will prove distinctly advantageous. Up till now, storage in bags has been found essential, in order to protect the fumigated seed from reinfection by moth. It has been shown that this caterpillar is an important means of spreading various rots, especially dry rot (*Fusarium*). A specially built storage house has been designed to protect against moth infection from outside and also

against high temperature and the resulting heat-rot. The plan of the building is as follows:— Double walls on all sides with air-space between; wire gauze over windows and door-space; roof of tiles, but underneath a ceiling covered with earth to a depth of 4 in.; ceiling open all round the edge and pierced by several openings in the centre; chimney to allow continual draught during hot weather; holes in floor connected with outside air by means of drain pipes partially filled with water; skeleton shelves to allow two layers of bags to be stored without in any way interfering with the aeration of either layer.

The store-room so built has been a distinct success in Poona and has to a large extent prevented rotting. The windows are kept open from 8 p. m. to 6 a. m. in the hot weather and then closed. The temperature has been kept as low as 82° F, when the temperature outside has risen to 101° F in the shade.

As a result of experiments made in various districts the following system appears to be advantageous. Within a week or 10 days of harvesting, the stock contained in bags should be fumigated with petrol vapour and subjected to selection for ring disease, dry rot, etc. The potatoes should then be re-bagged and if possible stored in a specially made house as described above. In the absence of special arrangements for a free draught of air, the open doors should be hung with canvas curtains kept moist during the hotter parts of the day.

332 - **Changes occurring in Oranges in the Course of Preservation.** - ANDRÉ, G., in *Comptes rendus de l'Académie des Sciences*, t. 173, No. 25, pp. 1399-1401. Paris, Dec. 19, 1921.

The author's experiments were made in the following manner. The oranges were divided into two groups of which one was subjected to analysis at once, while the other was superficially sterilised and preserved for 23 to 72 days in a sterilised vessel containing a small quantity of water and sealed with cottonwool. One sample was preserved in *vacuo*.

The respiratory strength of the oranges at ordinary temperature was measured by putting three whole fruits under a bell-glass in which a measured current of air circulated, this after its passage over the oranges traversing a solution of potash contained in two REISER tubes.

The results of the experiment showed that during preservation the process of ripening takes place in such a way that there is a marked diminution of acidity with a slight loss of sugar content. However, as these effects are also to be noted in *vacuo*, the diminution in acidity cannot be wholly attributable to oxidation but must partly be ascribed to a decomposition of a diastatic nature.

333 - **Causes of Inferiority of Manila Hemp Fibres (*Musa Textilis*) in recent Consignments.** - *Bulletin of the Imperial Institute*, Vol. XIX, No. 2, pp. 127-132. London, 1921.

Attention was drawn recently by a firm of fibre merchants to the fact that certain consignments of Manila hemp received in the United Kingdom had been found very deficient in strength. Samples of the defective

fibre were forwarded to the Imperial Intitute for examination and the results of the investigation are here described

Examination showed that the damage caused was due to a degradation of the cellulose, doubtless of bacterial origin, promoted by prolonged storage in a moist condition at a tropical temperature. This was confirmed by the fact that, on placing the fibre under similar conditions in the laboratory, the cellulose underwent further degradation and the fibre simultaneously increased in weakness. The fact that the storage of Manila hemp in a moist condition causes serious injury to the fibre is well-known in the Philippines, where hemp is most successfully cultivated, the rainfall is abundant and the bundles of wet fibre are packed indoors with the result that immense quantities of inferior fibre flood the market.

It is evident therefore that in order to avoid deterioration in Manila hemp, the utmost care should be exercised in drying the fibre and avoiding storage in a moist state.

Fermentation is liable to be more pronounced in the lower grades as they are not so well cleaned as fibre of the better qualities and contain more easily fermentable material in the form of parenchymatous tissue.

## PLANT DISEASES

### DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN

334 - **Heat-rot or Black Heart in Potatoes in India.** — See No. 331. of this *Review*.

335 - **Further Researches on the Dry Gummosis of Citrus Trees** (1). — SAVASTANO I., in *R. Stazione sperimentale di Vannicoltura e Frutticoltura, Agrigore, Bollettino* 12, pp. 1-6, figs. 9, Agrigore, 1921

An account is here given of the results of further studies of dry gummosis, "gommosi secca" or "mal secco", of citrus-trees.

Three districts where the citrus is largely grown were visited: the lemon-groves of S. Teresa-Riva (Prov. of Messina), the orange-gardens of Biancavilla (Prov. of Catania), and the orange and lemon gardens of the peninsula of Sorrento (Naples). In the last district the disease is of long standing and has assumed a more serious character of recent years.

In the plantations examined it was found that the malady occurs sporadically, that is to say, it attacks isolated trees and usually only a few branches are affected. It rarely happens that the disease assumes an intense form as at S. Teresa-Riva.

Lemon and orange-trees are equally liable to attack.

The author is of opinion that a careful investigation would reveal the presence of the disease in places which at first sight appear immune, especially in old or neglected citrus plantations.

The disease begins from two distinct points, viz., the apices of the young shoots of the season, and the woody shoots, branches and trunk. In both cases, it spreads downwards in the same manner as ordinary gummosis.

In the green branches the disease runs its course during the spring and summer. The tip becomes bent, turns yellow and withers; frequently there is exudation of a gummy liquid. The infection spreads down the branch and ceases on reaching a certain spot. Next year there is a recrudescence of the disease, which continues to descend and penetrates into the branch upon which the infected secondary branch is situated. The leaves and spines wither, the leaves becoming detached, while the spines remain. If the course of the malady is rapid, the infection spreads

---

(1) See *R.* Jan. 1922, No. 106. (*Ed.*)

the same year from the green to the woody branches, and the green branches usually wither completely.

In woody shoots, branches and trunks the disease follows the same course as ordinary gummosis, extending downwards between the bark and the wood, and the branches along its course wither. The bark retains its natural colour during the first period of the disease, so there is no sign of its presence underneath; herein dry gummosis differs from ordinary gummosis, as also in the fact that the bark does not finally become cracked but dries up and remains adherent to the wood. If a piece of the bark is removed, a gummy viscous liquid a little darker in colour than gum is found.

As the disease extends the foliage of the tree assumes a sickly aspect, and if it becomes aggravated the tree rapidly withers.

Occasionally the disease manifests itself in the form of patches, a gummy cortical spot forms round the bud which dries up. This is a localised form of gummosis.

Other fruit-trees, including those bearing stone-fruits, fruits with seed, and fig-trees, have been found in Sicily, Calabria and the Province of Naples to be attacked by a disease resembling the "mal secco" of the citrus.

This affection, according to the author, is to be attributed to the action of a bacterium, possibly *Bacterium gummi*. In California recently, *Bact. ultra-retiacens* has been found to be the cause of a disease which from its microscopic characters is undoubtedly dry gummosis.

The bacteria cannot pass from tree to tree, nor even from one branch to another without an inoculating agent; in the present case the cause of infection was the common fly which the author has often seen in the act of sucking the exudation from infected branches. At S. Teresa-Riva the trees first attacked were in the neighbourhood of a farm which was naturally infested with flies.

Grafting is a direct cause of dry gummosis; of the two commonest forms cleft-grafting is the more and shield-grafting the less dangerous, for as the disease is seated between the bark and the wood, it is easy to detect its presence with shield grafting, whereas it often passes undetected in clefts. The disease is aggravated in many ways such as: intense manuring or want of manuring, triennial, irregular dressing, excessive or unseasonable irrigation, neglect in triennial pruning and too infrequent tillage.

As regards the treatment of dry gummosis, the author advises: 1) cutting off the young branches as soon as they are found to be infected, this fulfils the double purpose of suppressing a new centre of bacteria and of preventing the further spread of the disease by insect agency, 2) the removal of the entire large branch, even if only partly withered, should the first operation have been delayed, and the removal of the branch below the diseased patch; 3) raising with a knife a small portion of the bark of the diseased shoots and branches in order to see if the wood is healthy; should it prove infected, the wood must be probed till healthy tissue is found and all the branch below this point must be cut off. If there are any small gum-coloured spots, or

patches, the branch should be cut back to the healthy part, 4) cutting below the graft, if the trunk proves to be diseased and allowing the Seville orange to grow again, after which it must be re-grafted, 5) felling and uprooting the tree, if the stock itself is contaminated. The hole must be left open and exposed to the sun in the spring another Seville orange-tree can be planted

#### DISEASES OF VARIOUS CROPS

- 342 - Observations on *Dothidiella Ulei*, an Ascomycete Injurious to *Hevea brasiliensis* in South America. CAYLA N. in *Le Trémouille Colmelle*, Year VI No. 49, pp. 17-19. Rochefort (January 1912)

In 1912 the author observed that the leaves of some young specimens of *Hevea brasiliensis* growing in the experiment field at Belém de Para (Brazil), had been attacked by a cryptogamic disease. The latter was attributable, according to GRIFFON and MAUBLANC, to the Ascomycete *Dothidella Ulei* Hennings (1)

By means of later researches made, not only at Para, but also in British Guiana and Surinam this disease was proved to be of very common occurrence in South America and all the details of the complete life cycle of the parasitic fungus were discovered

A scientific expedition made by the author in 1920 in Dutch Guiana confirmed the apprehensions already entertained as to the serious nature of the disease. The plantations of *H. brasiliensis* that had been made in this Colony are now abandoned and most of the trees have been felled, solely on account of the attacks of *Dothidella Ulei*. Even in the case of trees old enough for tapping, the leaves were so severely injured, the laminae being riddled with holes, that they were no longer able to discharge their functions. The trees are in a wretched condition and even if

(1) See R. July 1913, No. 885 (Ld)

they do not die, are reduced to such a pitiable physiological state as to be unable to produce more than very small quantities of latex of no economic value. The rapidity with which the disease spreads varies according to the growth conditions and is greatest where the soil is damp and insufficiently drained. Badly attacked trees are however also to be found growing on healthy well-drained soils, on the highest dykes of the polders, and even on estates at a fair altitude.

The cultivation of *H. brasiliensis* has now been completely given up in Surinam.

From the information collected by the author in British Guiana it is easy to foretell that the same fate, due to the same cause, is awaiting the rubber plantations in the Colony, for in 1919 the acreage under *Hevea* had decreased to half what it had been a few years before.

*Doth. Ulei* is the pest threatening any *Hevea* plantations that may possibly be established in Brazil in the future, and as the only economic solution of the problem of obtaining Brazilian rubber consists in growing *Hevea* on the banks of the Amazon, the necessary prophylactic measures must be adopted in making any new plantations. G. T.

343 - *Vermicularia Capsici*, a Deuteromycete Injurious to *Capsicum annuum* and *C. frutescens*, in Bihar, India. — DASTUR J. F., in *Memoirs of the Department of Agriculture in India, Botanical Series*, Vol. XI, No. 5, pp. 129-144, pl. 2. Calcutta, 1921.

The most serious disease of chillies (*Capsicum annuum* and *C. frutescens*), in Bihar is the die-back disease due to *Vermicularia Capsici* Syd., which causes considerable damage to the crop in years where there is continuous rain or high humidity in the latter half of September and beginning of October. In Bihar the disease first appears at the end of September or in the first half of October, when the plants are mature and have begun to flower. It spreads rapidly from one field to another and in severe cases of attack, the plants are either completely killed or so badly diseased that the yield of healthy fruits is negligible. The first nip of the cold dry weather gives a sudden check to the progress of the disease which eventually dies away; the plants then recover and put forth healthy new shoots. The critical period when the plants are subject to the attack of the disease is therefore of short duration, about four to six weeks.

Plants growing under shade have been observed to suffer very little from this disease. Late sown crops are also very little affected, but give a very poor return. Fruits that mature before the beginning of December become badly diseased, to the extent of about 35 %, but those ripening later escape the disease, the percentage of infected fruits after the middle of the month being negligible.

On the stem the attack as a rule starts from the growing point or the flower bud, and therefore the presence of the disease in the early stage of attack is marked by the withering and turning brown of the top of the affected branches. The plant dies back as the attack spreads downwards and when it reaches a fork the infection runs up the sound limb. In some

cases the attack starts, not from the growing point but from a wound on the stem. As the disease progresses, the infected part of the stem assumes an enamelled white colour and is sharply marked off from the healthy green bark by a black line running round the whitened area. The white of the diseased part is punctuated by scattered, black, bristly and minute elevations which are the acervuli of the fungus.

The fruits become visibly diseased when they turn red, but very seldom while they are still green. The first outward sign of infection is the appearance of a small black circular speck, generally sharply defined but at times diffused. The disease does not spread concentrically, but rather in the direction of the long axis of the pod, so that the originally circular spot becomes more or less elliptical. As the infection progresses, the spot is either diffused and black, greenish-black, dirty grey or is markedly delimited by a thick and sharp black outline enclosing a lighter black or straw-coloured area. Two or more diseased spots may become confluent, thereby destroying the regularity of the individual spots, but the delimiting black line is not always completely obliterated where the infected areas have united. Badly diseased pods lose their normal red colour and turn straw-coloured or in some cases pale white. The acervuli of the fungus are generally densely crowded together or else scattered; at times they are arranged concentrically. They project a little above the surface of the pod, and are bristly and carbonaceous. When a diseased pod is cut open the lower surface of the skin is found covered with minute, black, spherical elevations, which are the stromatic masses, or sclerotia of the fungus. In advanced cases the seeds are covered with a felt of white mycelium in which are embedded a few black or grey-green stromatic bodies. Infected seeds turn rusty in colour.

The author describes separately the microscopic characters of the disease on the stem, fruit, and seed and also gives an account of the cultural characters of the parasite. Cultures of the latter were inoculated with positive results on Chillies (seedlings grown in sterilised tubes containing moist plugs of cotton-wool; seeds removed aseptically from healthy pods, and growing points and flowers of plants raised in pots; mature pods and seeds); *Carica Papaya* (very young flowers and fruits), *Vigna Catjang* and *Dolichos Lablab* (fruits); *Solanum Melongena* (fruits), *Citrus* sp. The inoculation experiments showed that the plants take the infection only when the humidity is very high. If it is reduced below a certain limit, the progress of the disease is checked. Negative results were obtained by inoculations on mango (*Mangifera indica*), plantains (*Musa* sp.), French bean (*Phaseolus vulgaris*), sweet peas (*Lathyrus odorata*), onions (*Allium cepa*), sugar cane (*Saccharum officinarum*) and *Sorghum vulgare*.

It was at first supposed that seed selection would perhaps play an important part in controlling this disease, but the desired result has not been obtained under field conditions.

Experiments were also made in treating infected seeds with different strengths of copper sulphate solution and of formalin before sowing. The

rate of germination was however not higher, for it was found that the fungus hibernates in the seed.

Further experiments in controlling the disease were made in 1917, on eight plots under Chillies. From the results obtained the following deductions can be drawn: The disease appears after the end of the rains in the first and second week of October; it attacks plants only at a definite stage of their development viz, when the flowers have set, and disappears as soon as the cold weather starts in the beginning of November. Fruits maturing before the beginning of December are much damaged by the disease, but the percentage of infection on fruits that ripen later is small. It seems therefore probable that if a late-maturing variety could be successfully grown in Bihar, it would escape the disease.

As the *Vermicularia* disease is very common on varieties of Chillies grown locally, tests were made of seeds from Bombay and Peshawar, where it had not been reported, in order to see if plants raised from them were disease-resistant. Unfortunately these varieties did not grow well at Bihar.

The plants growing under the shade of trees or other crops suffer less from the attacks of *V. Capsae* and *Choanophora Cucurbitarum* (B. and Rav.) Thaxt. The latter parasite had never before been noticed on Chillies, but caused great damage. It started from the flower or leaf-bud, and led to wet rot of the shoot. Moisture plays a very important part in the development and spread of the disease, and hence plants growing under shade remain healthy while those in the open are affected. In October and November, night dews and ground fogs are heavy and the plants consequently become very wet at night and remain so for some time after sunrise; this high humidity is favourable to the spread of the disease. Under shade, however, there is very little mist or dew-fall and consequently the atmosphere is comparatively dry, or at least dry enough to check the spread of the disease. The experiments made did not yield any practical results from which the effect of shade upon the total yield and the percentage of diseased fruits can be determined.

The application of 2 cwt. superphosphate + 1 cwt. nitrate of soda per acre not only increases the total yield of fruits, but also reduces the percentage of diseased fruits. It is doubtful if the use of artificial manures is possible on account of the present inflated prices.

Two applications of 1 % Burgundy mixture are enough to control the disease, both on the plants and on the fruits. It is possible that only one application, if given at the right time, might be equally efficacious.

Healthy fruits from sprayed plants remain unspotted on drying, while those from unsprayed plants develop the disease.

Better results may be obtained by a combination of the application of manure and spraying with Burgundy mixture.

Late sown chillies suffer little from *V. capsae* and *Ch. Cucurbitarum*.

Judging from the observations of the last few years, it would appear that the die-back disease in Bihar becomes virulent when the humidity per-

centage in the second half of September (when the plants begin to flower), is on an average above 85. G. T.

344 - *Phyllosticta congesta*, a Deuteromycete Injurious to *Prunus triflora* in Georgia. — ROBERTS, J. W., in *Journal of Agricultural Research*, Vol. XXII, No. 7, pp 365-370, figs. 2, 1 plate Washington, D. C., 1921.

In June 1905, near Fort Valley (Georgia) pickings were made of fruits and leaves of the Japanese plum (*Prunus triflora* Roxbg.) which had been attacked by a disease very closely resembling the apple blotch (*Phyllosticta solitaria* F. and E.). On May 27 1908, the disease was again observed on both fruit and foliage of the Burbank plum in Georgia. It was found to be rather common in several orchards near Montezuma, and in some cases caused enough damage to injure seriously the market value of the fruit. On May 29 1917, other Japanese plum-fruits and leaves affected by the same disease were found in the same locality.

The varieties of *P. triflora* known as Abundance and Burbank were those attacked and an unnamed seedling also probably belonging to *Prunus triflora*.

The affected parts on the unripe fruit appear as dark-coloured raised areas, with fringed margins and are somewhat roughened by the presence of small blisters and depressions. As in the case of apple-blotch the skin often becomes ruptured as the fruit increases in size. On the ripe fruit the portions covered by pustules appear as irregular brown areas 3 to 6 mm. in diameter and consisting of an aggregation of 4 to 20 sunken spots, each of which is 1 mm. or less in diameter. At this stage, the spots have a peculiar light blue cast owing to the "bloom" of the ripe plum covering the brown epidermis. The diseased area is rather superficial, extending only slightly below the epidermis. The affected tissues become hardened and somewhat leathery, showing no tendency to decay. Small glistening pycnidia are produced in considerable numbers even in the younger spots. On account of its characteristic appearance on the fruit, the disease has been given the popular name of "plum-blotch".

On the upper surface of the leaf blades, the spots are angular, rather small, brown when young, but later becoming grey or silvery in colour. They may be numerous, as many as 200 sometimes appearing on a single leaf.

Usually one pycnidium only is present in each spot. Affected areas are also found on the petioles and on the veins of the lower surface of the leaf, especially on the midrib. On these the diseased areas are much larger than on the upper surface of the blade, and they are black and sunken. Pycnidia bearing spores are present in great abundance.

Pycnidia, apparently identical with those found in the fruit and leaves, were also seen in small light-coloured, often slightly sunken areas on the twigs.

The cause of plum blotch has been proved to be an organism identical with the fungus originally described by HEALD and WOLF as *Phyllosticta congesta* (1911), a parasite occurring on the leaves of the apple-tree in Texas.

In the spring of 1918, no spores were obtained in cultures, but inoculations were made by spraying the young fruits and leaves of the varieties Abundance and Burbank with bits of hyphae and sterile pycnidia suspended in sterile distilled water. The results were negative in every case. In 1919 spores obtained from apple-twig cultures and suspended in sterile distilled water were applied to the fruit, foliage and twigs of "Abundance" plums. When cultures originally obtained from plum fruits were used, two fruits both with two typical blotches, and three leaves with scattered spots were found. Each of these spots bore a single pycnidium with the characteristic stylospores of *Phyllosticta congesta*.

Like results were obtained by the use of cultures obtained from the leaves; one fruit showed three typical blotches with pycnidia and two others showed one; seven leaves were successfully infected. From all these artificially inoculated parts, the fungus was re-isolated and proved to be *P. congesta*.

No lesions were found on the twigs.

Inoculations made upon *P. triflora* with stylospores from pure cultures of *Phyllosticta solitaria* gave negative results in 1918, 1919 and 1920, although the stylospores were applied to fruit foliage, and twigs at frequent intervals throughout the spring.

No attempts to control Plum Blotch have yet been made. G. T.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS

345 - *Coccidae* from the Seychelles (1). — GREEN, E. F., and LAING, F., in *Bulletin of Entomological Research*, Vol. XII, Part 2, pp. 125-128, figs. 4. London, 1921.

GENERAL

The list contains the following species of *Coccidae* collected in different parts of the Seychelles.

1) *Pseudaonidia iota*, a new species found on the upper surface of leaf of *Eugenia caryophyllata*.

2) *Ps. aldabrac* sp. n., on bark of "Bois d'Amande";

3) *Aonidia obtusa* sp. n., on *Verschaffeltia splendida*;

4) *Ceroplastes rubens* Mask., on *Acrostichum* sp. Widely distributed in the Australasian region.

5) *Chionaspis subcorticalis* Green, on tomatoes, and *Sida* sp. Hitherto recorded from Ceylon only.

6) *Pinnaspis buxi* Bouché, on *Pandanus Seychellarum*; also on *Areca catechu*, an almost cosmopolitan species.

7) *Diaspis (Aulacaspis) flacourti* Rutherf., on *Flacourtia*; this is the first time that any figures have been given for this species, which was previously known from Ceylon only, where the insect was observed to cause irregular and conspicuous swellings on the older and mature branches of its host. G. T.

(1) See also R. Jan. 1917, No. 106 (Ed.)

- 346 - A Revision of the Genus *Locusta* L. (= *Pachytylus* Fieb.), with a New Theory as to the Periodicity and Migrations of Locusts. — UVAROV, B. P., in *Bulletin of Entomological Research*, Vol. XII, 2nd part, pp. 135-163, figs. 8. London, 1921

Not less than 16 "species" have been described by different authors as belonging to the genus *Locusta* L. (= *Pachytylus* Fieb.). The number has however been reduced by earlier revisers, who synonymised many species, but KIRBY (1910) still mentions seven distinct species.

The author's investigations have however clearly demonstrated the variability of the species of *Locusta* to an extent far greater than might have been anticipated. He has arrived at the conclusion that only two species can be distinguished, viz., *L. migratoria* L. and *L. pardalina* Walk., but the latter differs from *migratoria* in so many important characters that the author has made a new genus (*Locustana* g. n.) to include it.

From a careful examination of the interrelations between the three forms of *L. migratoria* (*L. migratoria* L., *L. danica* L., and *L. migratorioides* Rch. and Frm.), the author regards it as proved that the three forms cannot be separated specifically, and that they represent taxonomic units of lower grade than the species which must be called, according to the law of priority, *L. migratoria* L. They are however quite distinct from each other, though connected by transitional forms.

As regards the term to be applied to these forms, the author thinks phase (from the Latin *phasa*; abbreviation — *ph*) to be the most appropriate. He considers that *L. migratorioides* is without any doubt the oldest form ("phase") of the species, since its morphological and colour characters are far more constant than the more plastic *L. migratoria*, to say nothing of the extremely variable *danica*. The permanent breeding regions of *migratorioides* have never yet been investigated, all that is at present known regarding them being based on the records of the occurrence of its swarms; these data enable it to be stated that the best conditions for the development of this form seem to be present in tropical countries with a rather damp, hot climate, but undoubtedly not in forests. Since on the other hand these breeding grounds seem to be yet undiscovered, we may presume that they are not in open grassy land, which is easily accessible and mostly cultivated or populated. The author is of opinion that they are to be sought somewhere deep in the impenetrable jungles, overgrown with high grasses, reeds and similar vegetation. It is a well-known fact that the development of *L. migratorioides* in its permanent breeding regions is subject to periodical rise and fall, but the exact cause of the increase of locusts is entirely unknown. When the increase is at its height, large swarms are formed and the locusts emigrate to their permanent habitats. These emigrated swarms settle down and lay their eggs wherever they are compelled to do so by purely physiological reasons, and their progeny undergoes a transformation into the solitary-living phase (*L. danica*).

The latter phase is very plastic and easily adaptable and more progressive; it must therefore play an important part in the extension of the range of the species, gradually but steadily populating new regions. Being

a product of a mutation arising partly from some unknown internal cause, and partly from outer (probably climatic) influences, *L. danica* is naturally subject to sudden displays of atavism which result in the transformation into the ancestral phase, *migratorioides*. This phenomenon is no doubt much favoured, and often probably caused by the fact that the oviposition of *L. danica* takes place in conditions similar to those of the permanent breeding grounds of *L. migratorioides*. The gregariousness of the individuals of this latter phase is certainly one of the causes of the rapid increase of the insects and their swarms, and soon, in the course of a few generations, the size of the swarms reaches the maximum point, and emigration follows. In this way, the dispersal of the species goes on alternately by the gradual spreading of the *L. danica* phase, and by the periodical extensive emigrations of *L. migratorioides*. As a result, the species is now distributed all over the Eastern hemisphere, but the distribution of *L. migratorioides* is confined to tropical regions, while *L. danica* goes over to the Palaearctic region as well, where the swarming phase of the species is represented by *L. migratoria*. This latter fact might be satisfactorily explained by the impossibility of finding in the Palaearctic region natural conditions exactly like those of the tropical breeding grounds of *L. migratorioides* chiefly as regards a combination of heat and dampness. The nearest approach to these conditions are to be found in the great districts covered with reed-beds in the Palaearctic regions, the deltas formed by the Volga, Ural, Kouna, Terek, Arax, Sir-Daria, Amou-Daria, Ili, etc., discharging into the Caspian and Aral Seas and Lake Balkhash; to which the permanent breeding grounds of *L. migratoria* are now restricted. Though of a quite special character and in the summer recalling the tropics, the climatic conditions of these reed-beds are of course not tropical, and their effect upon the progeny of the *L. danica* breeding in them is not the same as that exerted by the tropical breeding-grounds of *migratorioides*. The reverse transformation of *danica* into a swarming phase does not reach the phase of *migratorioides*, but stops half-way at the *migratoria* phase. This seems to indicate that the transformation is due primarily to the direct influence of external conditions, its extent being proportional to changes in these conditions, but only precise laboratory experiments can help to clear up this complicated problem.

As in the case of *L. migratorioides*, the development of *L. migratoria* in the permanent breeding-grounds alternates with periodical emigrations followed by transformation into the *L. danica* phase. Although the author's observations are far from complete, they leave no doubt that temperature is a factor of the utmost importance in the movements of larval swarms of locusts. From observations made in the North Caucasus, the average temperature causing the first movements of the larvae varies from 13° to 15° C. Under ordinary circumstances, that is to say provided the sun shines all day, and no unusual changes of weather occur, the swarms keep moving the whole day and as a rule do not feed while on the march.

In the afternoon, when the temperature begin to fall, the velocity of the insects' movements decreases until the evening, when the swarm

stops. It is interesting to note that this evening cessation of movement occurs when the temperature is again near 13°-15° C. All the observations so far made by the author have convinced him that the movements of the locust swarms are not determined by lack of food and hunger, as is the generally-accepted theory, but depend entirely on thermotropism (probably negative), and on another, as yet little known tropism which is displayed by the tendency of each larva to repeat the movements of its nearest fellows and to move in the same direction.

When the locusts are fit for flight, single individuals begin to take wing and fly for a short distance, often circling above the still sitting swarm. Whenever a locust flies near enough to another that is at rest, the latter is disturbed and often takes wing and flies in the same direction; this is again another manifestation of the same tropism which causes the movements of larval swarms. Sooner or later the whole swarm flies off. At first the insects do not take a definite direction, but as each individual tries to follow its nearest fellow, a common direction of flight must necessarily result. If two swarms meet, they mix together and the swarm gradually grows larger. The larger the swarms become, the longer and more regular also become their flights, and at last they assume a definite direction, and the insects take leave of their breeding region altogether. What is the cause of this emigration? The generally-accepted theory is that locusts migrate from want of food. The author however states that, as in the case of the larvae, hunger cannot be the incentive to emigration, especially if we consider the physiological changes occurring in locusts during the period of emigration. On dissecting individuals taken from emigrating swarms, it is seen that the greater portion of the inner cavity of the body is occupied by air-sacs, which are only temporary organs reaching their highest development at the period of emigration and disappearing towards the end of this period when the developing reproductive organs take their place. During the emigration, however, the air-sacs are enormously large and all the other internal organs, including the stomach, are much compressed, thus rendering the insect almost incapable of taking food, at any rate in large quantities. This assumption based upon anatomical facts, is supported also by field observations, for the emigrating swarms, when they stop their flight do not in fact feed much, though incidentally they may cause great damage by merely cutting the stems of cultivated plants.

Anatomical researches reveal also that the fat-body is more developed in insects just before and at the beginning of emigration, and is almost exhausted towards the end of it. Probably locusts during this period live essentially on the food-reserves in the fat-body, being unable to take much vegetable nourishment, and consequently scarcity or lack of food has nothing to do with the emigration.

In short, there is at present no possibility of explaining the emigration by any causes other than physiological; the development of the air-sacs compels the insects to fly, and this impulse is strengthened by their gregariousness, that is by some kind of tropism which makes each individual

keep close to its fellows and follow their movements. The reduction of the air-sacs and the exhaustion of the fat-body determines the cessation of the emigration.

The theory of phases suggests the theoretical possibility of the control of *migratoria* by some means directed not against the insect itself, but against certain natural conditions existing in breeding regions which are the direct cause of the swarming phase. Observations made in South Russia show that even comparatively slight cultivation of breeding-regions leads to the desired changes, preventing the transformation from the inoffensive solitary phase (*L. danica*) into the swarming phase (*L. migratoria*).

As regards *L. pardalina* Walk (for which as has already, said been the author created the new genus *Locustana*) the observations made by J. C. FAURE, in South Africa, and the author's examination of a large series of specimens from the same country have proved that like *Locusta migratoria*, it has two different phases, which differ in colour and morphologically, but more profoundly biologically. There is a sort of parallelism between the variation from the swarming phase (*Locustana pardalina* Walk.) and the solitary inoffensive phase to which the author has given the name of *Locustana solitaria*. The relations existing between *Locustana pardalina* and *L. solitaria* as regards morphological characters, the coloration in the larval and the adult stages, and the behaviour of the insect are very similar to those observed by the author in the case of *Locusta danica* and *L. migratoria*. J. C. FAURE's conclusions, which he arrived at quite independently of the author's work on *L. migratoria*, give a very strong support to the theory of phases as a direct cause of the periodicity of these locusts. It seems that in *pardalina* the transformation of solitary individuals into the swarming phase takes more than one generation, but the actual causes of the transformation are in this case as obscure as in *L. migratoria*. Data as to the migrations of the fliers and the fate of the migrating swarms of *pardalina* are not yet available. Further investigations of this problem closely connected with the careful study of all conditions of breeding-grounds, are extremely important from the point of view of locust control in South Africa.

347 - *Isaria Eristalidis*, a Hyphomycete living on the Dipteron, *Eristalis tenax*, in Japan. — YASUDA, A, in *The Botanical Magazine*, Vol. XXXV, No. 420, pp. 219-221

MEANS  
OF  
CONTROL

This article contains a description of three new species of *Isaria* found in Japan living on insects: *I. japonica*, *I. Cosmopsaltriae* and *I. Eristalidis*. The last was observed on pupae of *Eristalis tenax* L. (European Drone-fly) (1), in the Province of Harima.

346 - **New Species of Indian Braconidae.** — LYLE, G. T., *Bulletin of Entomological Research*, Vol. XII, Part. 2, pp. 129-132, figs. 2. London, 1921.

The author gives a description of the following species which are new to science :

1) *Microplitis similis* sp. n., a parasite of *Agrostis ypsilon* L., collected at Pusa and Sabour (Bihar and Orissa), and at Mokamah (Bengal) ;

2) *Microplitis eusirus* sp. n., reared from *Achaea janata* L., at Pusa ;

3) *Rhogas (Heterogamus) percurrans* sp. n. also reared from *A. janata*, at Pusa. G. T.

349 - **Control Measures against the "Pink Boll-Worm" (*Gelechia Gossypiella*) of the Cotton Plant, in Egypt.** — See No. 263 of this Review.

350 - **The Control of the Olive Fly (*Dacus oleae*) during 1920, in Greece.** — ISAAKIDES, C. A., Report of the work of the Phytopathological Service in Controlling *Dacus* during the Year 1920 in Chalcidice, Pelion and Messenia and of the results obtained, 48 pp., pl. 3 Athens, 1921.

In Greece, the olive-fly (*Dacus oleae*) causes an average annual loss of 25 000 000 "okes" of oil (1 oka = 2.755 lb), which at present price means a loss of 100 000 "drachmas" (1 drachma = 9<sup>23</sup>/<sub>64</sub>d. at par).

For a long time and on many occasions experiments in controlling the pest had already been made on a small scale ; mixtures with an arsenical base having been used with encouraging results, but it was not till 1920 that this method was adopted over an extensive area and for a really large number of olive-trees.

Operations on a larger scale against the olive fly were facilitated by the institution (by virtue of law No. 1366, of 1918) of the "Olive Bank" which was founded for the express purpose of providing the means of protecting and freeing the olive-tree from its animal and plant enemies. The funds of this Bank are supplied by : 1) a special tax on olives and olive-oil ; 2) a State grant ; 3) the profits from re-selling the ingredients, instruments and all apparatus necessary for controlling parasites. By Royal Decree, the special additional tax is levied on districts which already pay the tax on olives and olive-oil and where the communes have requested through their municipal councils that this tax should be imposed, in order that they may enjoy the advantages offered by the Bank.

The amount of this extra tax is apportioned in such a manner that part of the expenses of the Bank is defrayed by the State, and part by the olive-growers. The duties of the Bank consist in buying and distributing the ingredients and apparatus, giving information respecting the control of the parasites of the olive-tree and in itself carrying out the necessary treatments and thus setting an example to others.

The organisation and supervision of the scientific work of the Bank are entrusted to the Government Phytopathological Service.

It was decided in 1920 to adopt the usual measures against the Olive-fly at Polyghyros (Chalchidice), a district where there are about 150 000 olive-trees, in the Pelion district (about 2 700 000 olive-trees), and at Kyparissia, Erani and Platamodes (Messinia) (about 7 000 000 olive-trees), the total number of trees to be treated being 3 500 000.

On account of their size, the territories of Pelion and Kyparissia, Erani and Platamodes were divided into several sections in order to facilitate the control campaign. From one to four gangs of workers were appointed to each section, their number being proportionate to that of the trees and such as to allow each treatment to be applied within about a month. The work was directed and carried out entirely by an expert Staff under the general supervision of the Phytopathological Service.

According to the recommendations of the Service, the olive-trees were to be given during the 1920 season three successive sprayings, after which three vessels containing the insecticide mixture should be provided for every hundred olive-trees.

This mixture was composed of sodium arsenite 3  $\frac{1}{2}$  kg. ; molasses 110 kg. ; water 10 hectolitres.

According to the instructions given, about 320 gm. of the mixture were to be used for a tree of average size ; it was however found at Polyghyros, that 250 gm. were enough, and that larger amounts scorched the young leaves and shoots and also the fruits, without proving any more destructive to the olive flies.

In Pelion on the other hand, where the trees are larger, it was thought advisable to spray each tree with 320 gm. of the mixture the first time, 460 gm. the second, and with a still larger quantity for the third. After a few days' practice, the workers are able to spray each tree with the required amount of the mixture and one man can treat about 800 trees a day. In the case of the first and second sprayings, the mixture must be spread upon the interior of the foliage, but the third spraying must be directed upon the exterior of the tree, where the olive-flies are to be found at that time.

In all the zone to be treated, the first spraying must be begun towards the second fortnight in June, the lowest lying districts and those most attacked by the insect being first treated.

The second spraying begins towards the end of July and lasts about one month. The third treatment was begun at Polyghyros on August 22nd and finished on September 6<sup>th</sup>. In Pelion and Messenia, it was begun early in September and prolonged until the end of the month or the beginning of October. In every case untreated olive-trees were left as controls. Difficulties of a practical nature made it impossible to place the three series of vessels among the trees. As the three sprayings had proved satisfactory and are easier to carry out than fixing the vessels in the trees and keeping them replenished with the mixture which quickly evaporates, it was decided to substitute a fourth spraying for this part of the treatment. This spraying began on September 21 and finished on October 8 at Polyghyros and was generally adopted. In Pelion,

however, it lasted throughout October, but was only carried out in the districts most exposed to attack, this being all that was possible owing to the rains. In Messenia a few trees only were sprayed four times.

In spite of all the precautions adopted, it proved impossible to prevent all the injuries inseparably connected with the use of the insecticide, though considering the extent of the area in which the control was carried out, the cases of burns among the workers and transport animals were not frequent.

The application of the mixture with a molasses base caused the disappearance of ordinary flies and was also efficacious in destroying another Dipteron which is injurious to the olive-trees, *Lasioptera berlesiana* Paoli, known in Greece under the popular name of "xerouvoula". On the other hand, as was proved by special experiments, the mixture is harmless to bees.

Most satisfactory results were obtained by the control operations carried out in 1920 in Chalcidice, Pelion and Messenia. As a rule, 50, 80 and even 100 % of the fruit of untreated trees was attacked by the olive-fly, whereas all the trees that were sprayed remained perfectly immune. No occurrence of "fumagine" was observed as a result of the dachicida sprayings in any of the districts where the treatment was adopted.

A total of 8 341 kg. of arsenite of sodium and about 260 tons of molasses were used. The cost of the treatment at Polyghyros, Pelion and Messenia amounted to 622 563 drachmas (1 drachma = 9 <sup>33</sup>/<sub>64</sub> d. at par).

The larger crop of better quality obtained in 1920 owing to the control operations, brought in an immediate return of about 20 000 000 drachmas to the olive-growers, while the state benefited to the amount of over 800 000 drachmas, this being the tax on the part of the crop that had been preserved from the attack of *Dacus oleae*. INSECTS, ETC.  
INJURIOUS  
TO VARIOUS  
CROPS

351. *Phthorimaea operculella* in Tunisia (1). — POUTILRS, R. in *Bulletin de la Société entomologique de France*, No. 2, pp. 30-31. Paris, 1922.

*Phthorimaea operculella* Zell, was found in October 1921 in Tunisia, but only at Sousse, where it had been introduced a few weeks previously. From enquiries made on the spot, it appears that this Microlepidopteron was disseminated in the district by some thousand kilos of Maltese potatoes which had been put on the market for "seed". Under such special conditions *Phthorimaea operculella* might easily spread, but as a very small quantity of potatoes are produced in Tunisia and these are quickly consumed, the insect will probably have little chance of living long or multiplying in the country. Further the Tunisian Agricultural Authorities have adopted certain measures of supervision which justify the hope that even if the pest succeeds in establishing itself in the neighbourhood of Sousse, it will be possible to destroy it on its first appearance elsewhere, or at least to prevent its spreading over a wider area.

(1) See R. Feb. 1922, No. 220. (Fd.)

If the infected potatoes were really grown in Malta from which they were shipped, the fact is one of considerable interest, as Malta will in that case have to be added to the list of places where *Pht operculella* is already known to work havoc

352 - "Potato Moth" (*Pthorimaea operculella*) in India. See No 351 of this Review

353 - *Neurotoma nemoralis*, a Hymenopteron Injurious to the Peach-tree, in France. — PAILLOT, in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol VII, No 38, pp 827-831. Paris, 1921

The existence of the peach tree orchards in the Rhone valley is seriously threatened by the Hymenopteron, *Neurotoma* (*Lyda*, *Pamphilus*) *nemoralis*. So far the damage seems to be confined to the territory of the Communes of Saint-Rambert d'Albon (Drôme) Adancette (Drôme) and Saint Désirat (Ardèche), but the advance of the insect is rather rapid. At Saint-Rambert the area of peach orchards utterly destroyed was three to four hectares in 1920, but rose to fifteen hectares in 1921, and it is probable the invasion will extend still further in 1922.

The author, from his own observations and the information collected in the course of his enquiries, is inclined to believe that the first appearance of *Neurotoma nemoralis* is confined to small centres that quickly extend from year to year. The development of these centres should be carefully watched and the insects destroyed before they have time to spread further.

In 1921 the moths began to fly towards the end of April but the chief laying season never begins before the 10th of May. The larvae hatch out six or eight days after the eggs are laid according to the temperature, and attain their full size in about a fortnight, when they burrow into the soil in order to pass the winter underground.

In 1921 the author began at Saint-Rambert a series of experiments in treating the centres where the largest number of moths had been seen on the wing and many eggs had been deposited in the leaves.

Experiment I — Nicotine and soft soap

Nicotine (100 gm per litre)	1 1/2 litre
Soft Soap	2 kg
Water	100 litres

The treatment was carried out on May 16th with a knapsack-sprayer, throwing a jet of 2 m, the hatching out of the larvae had just commenced.

Experiment II — *Quassia amara* and soft soap

<i>Quassia</i> (in chips)	1 kg
Soft soap	1 500 kg
Water	100 litres

The decoction of *Quassia* is prepared by boiling the chips for two hours in several litres of water. The treatment was carried out on the same estate where the nicotine had been sprayed previously.

**Experiment III — White hellebore powder and gelatine :**

White hellebore (rhizome) . . . . .	1.250 kg.
Gelatine . . . . .	100 gm.
Water . . . . .	100 litres

Treatment carried out on May 14th under the same conditions and in the same orchards that had been sprayed with the other two mixtures.

**Experiment IV. — Nicotined lime.**

A powder prepared by slaking quick lime with weak tobacco juice. An ordinary sulphating apparatus is used. Treatment carried out May 14th.

By way of experiment a late spraying was made with arsenate of lead towards the end of May, in an orchard that had suffered greatly from the ravages of the insect. It was most efficacious, but unfortunately the use of this insecticide cannot be recommended, as the French law prohibits the employment of arsenical mixtures after the flowering season, in the case of trees bearing stone-fruit.

The results of the spraying, as observed on May 28, were as follows :

Peach-trees treated with nicotine, *Quassia* and hellebore at the beginning of the hatching out of the larvae : condition very good ;

Peach-trees treated with nicotine several days after the larvae hatched out ; less satisfactory ; a fairly large number of living caterpillars present.

Peach-trees dusted over with nicotined lime . little different from the controls.

The formulae most to be recommended at present are those with a nicotine and *Quassia* base ; hellebore is efficacious but somewhat difficult to obtain. If the trees are very severely attacked, two sprayings are necessary at intervals of 5 to 6 days ; the first should be carried out as soon as the larvae begin to make their appearance. G. T.

354 — The Coccid, *Chrysomphalus aurantii*, in the Colony of Kenya, East Africa. — DRY, I. W., in *Bulletin of Entomological Research*, Vol. XII, Part I, pp 103-104. London, 1921

The presence of *Chrysomphalus aurantii* Mask. on the citrus-trees of the Colony of Kenya was reported for the first time in 1914. It is known that the Coccid was introduced by at least one consignment of imported citrus fruit which as it was provided with a certificate of immunity by the exporting country, had been admitted into the Colony without inspection. Thus it appears probable that *Chrys. aurantii* is not indigenous to Kenya. For this reason efforts were at once made to prevent its establishing itself in the Colony and with the hope of saving the citrus trees, and of preventing the pest attacking the coffee plantations, which are of far greater importance to Kenya than the orange and lemon groves, all importation of citrus fruits was at once prohibited and owners of citrus trees were required to destroy any that had been attacked by the Coccid.

Since 1917 the citrus gardens and nurseries have been inspected, and the owners requested to communicate the results of their investigations. It was ascertained in this way that *Chrys. aurantii* was widely distributed in the Colony, where it had attacked a large number of trees.

The insect was not only found on citrus trees, but also on rose-bushes, the apple-tree, plum-tree and on sisal.

Laboratory and field experiments have shown that so far the coffee trees have fortunately remained free from the pest.

The life-cycle of *Chrys. aurantii* has been followed in citrus fruits, but unluckily the extermination of the insect appears to be practically impossible. Since fumigation would be too costly, spraying is recommended as the best means of control.

G. T.

355 - *Rhagoletis suavis*, a Dipteron Injurious to *Juglans* spp., in the United States. -- BROOKS, F. D., in *United States Department of Agriculture, Bulletin* No. 992, pp. 1-8, pl. 1. Washington, D. C., 1921

*Rhagoletis suavis* (Loew) probably occurs fairly generally throughout the area of the natural distribution of *Juglans nigra* and *J. cinerea*. It has been found in the following States of the North American Confederation: Massachusetts, Minnesota, Indiana, Connecticut, New York, Ohio, District of Columbia and Virginia

This dipteron chiefly attacks the husks (epicarp), of *J. nigra* and *J. cinerea*. The author has however reared adult specimens of *Rh. suavis* from the husks of *J. regia* and *J. Sieboldiana*. Amongst these hosts the black walnut (*J. nigra*) and the Persian walnut (*J. regia*) are preferred to the others, probably on account of their thicker husks.

In the case of *J. nigra*, the eggs of the parasite are usually deposited so late in the season that the larvae do not prevent the nuts from ripening and dropping normally. Thus while apparently all the eggs are laid in nuts on the trees, the development of the larvae and the blackening of the husks which results from their feeding takes place chiefly in fallen nuts. In *J. regia* however the eggs appear to be laid earlier in the development of the nuts. Walnut-trees in Maryland and Pennsylvania were seen shortly before the crop ripened, to have a large percentage of the husks of the nuts blackened and the surface covered with a gummy exudation from the larval injury within. Some of the infested *J. regia* fruits drop prematurely, and others hang to the branches until after the sound nuts have fallen. In nuts attacked before maturity, the development is arrested and the kernel becomes unfit for use. The injury is thus threefold: the quality of the kernel is impaired, the husk sticks to the shell in the hulling process and the shell itself is discoloured making the nuts unattractive for market.

The author gives a detailed description of the different stages of the insect's development and of its habits.

Hitherto one parasite only of *Rh. suavis* has been discovered; this is a hymenopteron, *Aphaereta auripes* Prov. reared from the puparia of the Dipteron at Amherst (Massachusetts). A Rhynchote (*Lopidea*

sp.) was surprised by the author with its beak inserted through the skin of a black walnut sucking out the contents of a batch of freshly-laid *Rh. suavis* eggs.

In 1920 experiments in controlling the husk-maggot (*Rh. suavis*) were made with lead-arsenate sprays during the first ten days of August on two groves of *R. regia* laden with fruit, the one in Maryland and the other in Pennsylvania.

At New Windsor (Maryland), 3 pounds of lead-arsenate paste to 50 gallons of water were used for spraying; at West Willow 1 ½ pounds of lead arsenate powder to 50 gallons of water were applied; and some of the trees were sprayed with a lead-arsenate solution to which enough molasses had been added to give the liquid a slightly sweetish taste.

The trees of both groves had borne the previous season but the crops had been seriously injured by the larvae of *Rh. suavis*.

At the time the groves were sprayed the adult Diptera were appearing on the trees, and at West Willow a close examination of the nuts disclosed one batch of freshly laid eggs.

The nuts of the trees that had been sprayed at New Windsor were examined and counted just before the crop was gathered, and it was found that only 4 % of the nuts had been destroyed by the larvae, while at least 60 % had been attacked the previous year. At West Willow it was estimated that the conditions were 75 % better than the year before when no treatment was given. No Persian Walnut trees were found near either place that were suitable for use in checking the definite results of the spraying, but a comparison of the sprayed nuts with those produced by the same trees the previous season, together with the known abundance of the flies that appeared early upon the sprayed trees indicates decidedly beneficial results from the treatment.

Adult specimens of *Rh. suavis*, when confined in roomy wire screen cages, were also observed to feed freely on sweetened water to which sufficient lead arsenate had been added to give the liquid a milky colour though it must be admitted that these flies succumbed very slowly to the poison. More tests of this treatment must be made before it can be recommended unreservedly as an effective and sure method of control for this pest.

G. T.

356 - *Chloryta lybica* n. sp., a Rhyncote Injurious to the Vine in Libia — Dr. BERGEVIN, F., and ZANON, V., in *L'Agricoltura Coloniale*, Year XVI, No 2, pp. 55-64, figs. 4 Borgo S. Lorenzo, February 1922

In 1918, V. ZANON observed for the first time some isolated vine-stocks in a vineyard at Berka (Benghasi), which had yellowish second shoots (*feminelle* and *sottofeminelle*), although the July foliage as a rule quickly assumes the dark green colour of the spring leaves.

In the following years, the vines with yellowish leaves did not occur isolated, but in groups scattered throughout the vineyard; and also, whereas at first the lighter colour of the young leaves was due to the presence of yellow patches, these now extended over the surface of the

leaf which became wrinkled and curled, the edges being affected with necrosis, and finally fell. In addition all these second shoots were rachitic, and their internodes were shortened, at the same time a superproduction of buds was observed.

This affection had also been noticed in other vineyards at Berka, although no reason could be assigned for it until in August 1920, ZANON while examining a similarly affected vine on a trellis at Püehat, found upon the lower surface of its leaves a light-green Rhynchote only a few millimetres in length and possessing great powers of jumping. After investigating all the vines that he knew to be abnormal, he became convinced that the affection was due to the Rhynchote which punctured the leaves thus causing them to turn yellow and fall. The puncture also acted as a stimulus causing the production of superfluous buds.

ZANON suspects that the supposed outbreak of Bramble-leaf recently reported in Tripolitania (1) was due to the effects of the attack of this Rhynchote which L. de BRIGLIN regards as a species new to science and describes under the name of *Chlorita lybica* G. T.

357 - **New Species of Curculionidae attacking Forest Trees in India.** — MARSHALL, G. A. K., in *Bulletin of Entomological Research*, Vol. XII, Part 1, pp. 165-180, figs. 1-13 (London 1921).

In this paper the author describes the following *Curculionidae*:

1) *Sympiezomias bicolor* sp. n. found in several parts of the Province of Madras feeding on the leaves of young teak (*Ictona grandis*) and in some cases delimiting the trees.

2) *Ilcides dipterocarpi* sp. n. bred from seeds of *Dipterocarpus* at Dehra Dun (United Provinces).

3) *Mecistocercus fumosus* sp. n. on *Pinus longifolia* and bred from the latter host plant in different places in the United Provinces and Punjab.

4) *Rhadinomerus bombacis* sp. n. bred from *Bombax Malabarica* at Pathri, Sarahanpur (United Provinces) and at Singhbhum (Bihar and Orissa).

5) *Rh. diversipes* sp. n., bred from *Eugenia Jaman*, *Shorea robusta* and *Shorea* sp. in several parts of the United Provinces.

6) *Rh. malloti* sp. n. bred from *Mallotus philippinensis* at Lachiwala, Dehra-Dun (United Provinces).

7) *Rh. subfasciatus* sp. n., bred from *Shorea robusta* and *Shorea* sp. respectively at Jhabarkhet, Dehra-Dun and Kotdiawara, Lamsdowne Division (United Provinces), and from *Eugenia* sp. at Thano Siwalik Hills (Punjab).

8) *Rh. buteae* sp. n. reared from *Butea frondosa*, at Rani Range Siwalik Hills (Punjab).

9) *Ospilia odinae* sp. n. bred from *Odina Wodier* and *Cassia Fistula*, in several places in the United Provinces. G. T.

(1) See R. Nov. 1921 No. 1174 (1d).

- 358 - **The Tussock Moth (*Lymantria monacha*), in Valais, Switzerland.** — BARBEY, A. in *Journal forestier suisse*, Year LXXIII, No. 2, pp. 21-25, 1 pl. Berne, February 1922.

The Tussock Moth (*Lymantria monacha*), made its appearance in Haut Valais, in 1921, in the lower part of the Cooches Valley (Gomserthal), where the Macrolepidopteron was on August 5th suddenly found to have invaded the Communal forest of Ernen. The zone attacked was situated at an altitude varying from 950 to 1000 metres and had a superficial area of about one hectare. It had been planted some 60 to 80 years previously, with *Picea* (Spruce) asto  $\frac{9}{10}$  and *Pinus sylvestris* (Scots pine) asto  $\frac{1}{10}$  all the trees were in good condition at the time, some of the spruces having attained the height of 24 metres.

The rains that fell towards the middle of August had hindered the insects from swarming and laying, but some of the moths had previously succeeded in depositing their eggs under the scales and within the crevices of the bark of the trees, choosing by preference those that had been severely damaged by the caterpillars. On September 15th countless clusters of eggs were found surrounding the lower portions of tree trunks of every size in the infested zone. On some trees a cluster was found on an average on every square decimetre. On the spruces and Scots pines alike, chrysalids and the remains of caterpillars and adult insect were discovered bearing traces of the attacks of their natural enemies.

The most likely explanation of this invasion would seem to be the following: the Tussock moth, which is of sporadic occurrence in Switzerland, succeeded in 1920 or possibly in the preceding year, owing to favourable meteorological conditions in penetrating into the Rhone valley from the basin of the Léman. Some couples of the Macrolepidopteron meeting in the Grengiols pass found their way, into the Forest of Ernen. The exceptional warmth of the spring and early summer of 1921 following a very mild winter caused the eggs that had been deposited in large numbers in July 1920, to hatch out. It is also possible that this part of the Conches Valley may have harboured this macrolepidopteron for years though the insects may not have succeeded before the summer of 1920 in laying a large quantity of fertile eggs.

Orders were at once given to fell during the winter all withered or half-withered trees having a great number of egg-clusters on the scales of their bark. As all trees attacked by the Tussock moth are irretrievably lost, these measures were adopted to prevent any subsequent incursion of xylophagous insects which generally act as secondary enemies.

The infested bark must of course be scrupulously burnt, and a careful supervision exercised over the surroundings of the infected zone, in order to ascertain that the invasion has been effectively checked. (G. T.)

- 359 - ***Platypus omnivorus*, a Beetle Injurious to Wood, in New South Wales.** - FROGGART, W. W., in *The Agricultural Gazette of New South Wales*, Vol. XXXII, Part 9, pp. 645-648, 1 pl. Sydney, 1921.

*Platypus omnivorus* Lea (the shot-hole borer), which was first recorded from Tasmania, is widely distributed through the New South

Wales coastal forests where it is commonly known as "brushes", or "cedar brushes".

The beetle is not noticeable during the winter months but is very active in December, January and February. It not only penetrates into the sap-wood but bores into the solid material of the logs for some distance. It also attacks newly-sawn boards while drying, but when after exposure for a month or so, the sap dries out, the timber loses its attraction and the borers leave it alone.

The principal timber, damaged by these beetles are beech (*Trochocarpa laurina*), blackwood (*Acacia melanoxylon*), corkwood (*Schizomeria ovata*), sassafras (*Doryphora sassafras*) and coachwood (*Cratogeomys apetalum*).

The general opinion of investigators is that preventive measures are the only means of combating insects of this type, such measures consist in the removal of all dead and dying trees from the forest area, and their destruction before the beetles develop and emerge from the infested wood.

When timber has been cut and stacked it is still liable to infestation until it is quite dry. The beetles can, however, be kept away by the use of carbolic sawdust sprinkled beneath the stack and between the layers of boards and battens as they are stacked. A 5% solution of water and carbolic acid is mixed in a bucket of sawdust and the moist sawdust is freely sprinkled over the timber. A saw miller to whom this method of treatment was recommended has had no further complaints to make of damage by the beetle to his timber since he has adopted these precautions.

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION

360 - **The Present Position of Agriculture in the Philippine Islands.** — HERNANDEZ, A., in *Government of the Philippine Islands, Department of Agriculture and Natural Resources, Twentieth Annual Report of the Bureau of Agriculture*, pp 1-65, pl. LIII, Manila, 1921.

There has never been greater prosperity among farmers nor has there been a year in which greater progress has been made in agriculture in the Philippines than in the year under review (1920). Many causes have contributed to this result but the most conspicuous are the following: 1) The Food Campaign combined with the Rice and Maize Fund which has greatly stimulated increased production; 2) the introduction of modern tractors and gang ploughs in the sugar-growing areas; 3) seed selection; 4) the importation of pure bred sires and consequent improvement of livestock; 5) the establishment and remarkable growth of Rural Credit among small farmers; 6) the establishment of poultry and swine stations and provincial and municipal plant nurseries; 7) the increase in the number of farm advisers and agricultural inspectors; 8) the organisation of a plant quarantine service to prevent the introduction of plant pests through importation.

During the period 1910-20, there was an increase of 45 % in the area planted with the 6 principal crops, viz. rice, maize, Manila hemp, sugar, coconuts and tobacco. For the 5 years 1915-19, the average yields of these crops per hectare were as a whole 21 % greater than those for the preceding 5 year period, and the yield per hectare in 1920 was 4 % above the average of the period 1915-1919, notwithstanding the damage sustained through typhoons and floods. This shows the advance made both

DEVELOPMENT  
OF  
AGRICULTURE  
IN  
DIFFERENT  
COUNTRIES

in area and in yield, but an even greater gain has been made in value. The value of these 6 crops has steadily increased from 159 055 329 pesos (1 peso = 50 cents U. S.) in 1915 to 687 131 502 pesos in 1920. Much of this increase in the value of the products is undoubtedly due to prevailing high prices during and after the war, but a large part is due also to the increase in acreage and yield.

The results obtained during 1920 were significant, not only as showing that better methods have produced better yields, but also as evidence of the able manner in which the farmers continued their cultural operations in the face of adverse weather conditions and floods, coincident with the time for planting and transplanting rice, and also the shortage of hired labour.

RICE (1). — The yield was 8 % greater than in that of the previous year and 33 % more than the average for the 5-year period 1915-19. The production of cleaned rice amounted to 1 019 400 metric tons and was nearly sufficient to supply the demand for local consumption, only 11 000 metric tons being imported.

SUGAR CANE. — The area planted was 1 % less than the previous year (197 403 hectares in all) but the yield was 3 % greater and the highest hitherto recorded, the total production being 423 580 metric tons; the increase in value was phenomenal and amounted to 114 %.

An experiment is in progress to determine which varieties will give good results under the local soil and climatic conditions existing in the La Carlota district, with particular reference to growth of plants and tonnage of cane per hectare.

Analytical tests are also in progress to ascertain the commercial value of old and also of newly introduced varieties.

Acclimatisation and quarantine work is being carried on, and with reference to the first, the varieties Cebu purple and Hawaii-109 promise well. Seed cane propagation, distribution and demonstration work have done much to show the Philippine planters the value of improved methods of cultivation. Experiments are being conducted also to determine the effect of wider or of closer planting on the yield of a given variety. Fertiliser experiments are being conducted with the Negros Purple variety to determine the value of lime and native fertilisers; burned lime, cane bagasse ashes, farmyard manure, filter press mud or cake, copra meal and bat guano have been applied in varying quantities. The value of the "Aquila" fertiliser and other varieties is also being tested.

From the breeding experiments so far conducted, the young plants from the seeds of Hawaii-20, Hawaii-27 and "Mountain" (large, white-unidentified) are showing the best results.

MAIZE. — The 537 135 hectares planted in 1920 gave a yield of 552 907 350 litres of grain; the highest yield obtained during the past 10 years.

(1) See No. 409 of this *Review*. (Ed.)

**TOBACCO.** — This crop also reached its maximum production for the past 10 years, the yield amounting to 64 893 metric tons of leaf from 101 123 hectares, as compared with 56 498 metric tons from 73 859 ha. in 1919, i. e. an increase of 15 % in production, 37 % in area and 52 % in value.

General cultural and seed selection work, acclimatisation of foreign varieties and other experiments have been carried on at Dammas and the newly established Cotabato Tobacco Station.

**COCONUTS.** — This crop has also created a record during the year, both with regard to the number of trees and the production of copra, which amounted to 361 605 metric tons and consisted of 382 tons of steamed copra, 197 693 tons of smoked copra and 163 530 tons of sun-dried product.

**MANILA HEMP.** — The area occupied was 559 356 hectares: 4373 ha. more than in the preceding year. The production increased from 148 341 metric tons to 165 081 tons.

For all these crops it is anticipated that there will be a further increase in production with the exception of the Manila hemp, the fall in prices having discouraged growers.

Among other crops, reference is made to : maguey (*Agave Cantala*) — with the increasing demand for substitute fibres, 30 567 hectares were cultivated as compared with 28 465 ha. in 1919, and the production was 18 178 metric tons as against 12 318 tons.

**VEGETABLES AND ROOT CROPS.** — The total area devoted to these crops was 141 211 hectares.

**LIVESTOCK.** — Steady progress has been made, showing that carabaos (buffalos) have increased 96 % (actual numbers 1 388 244) ; cattle 178 % (678 525) ; horses 79 % (255 380) ; hogs 90 % (3 129 776) ; goats 73 % (731 849) ; sheep 89 % (168 181).

The principal research work has been in connection with rinderpest. A vaccine has been prepared which will render highly susceptible animals, immune when given in 10 cc. doses. Calves and animals not full grown are given from 8-15 cc. Nearly all the inoculations so far made have proved successful. Experiments also with a semi-dry vaccine have given gratifying results. Hog cholera vaccine is being developed along similar lines. Immunisation experiments have been made with carabaos against tetanus, to ascertain their availability as producers of anti-tetanic serum.

An account is given of the general work and administration of the Bureau of Agriculture and the activities of its various departments. Attention is drawn to the excellent work done by the Demonstration and Extension Division which has done much to initiate the farmers into the modern practical cultural methods elsewhere proved successful.

The Fibre Division has conducted a campaign throughout the year to improve the methods of stripping and preparing fibre for the market "Prieto" fibre stripping machines were operated to demonstrate the practicability of their use for stripping maguey and sisal. Other similar machines have given good results.

M. L. Y.

361 - **Agriculture in Corfu.** — MALAMATIONOS, C. J., in *L'Economiste d'Athènes*, Year 1, No. 18, pp. 273-275. Athens, Jan. 19 to Feb. 1, 1922.

The chief crop in the island of Corfu which has an area of 240 square miles and a population of 90 000 inhabitants, is the olive which is grown on the hills. The oil is superior to the Cretan though slightly inferior to that of Mytilene. It is estimated that there are 2 559 000 olive trees in Corfu on an area of 170 000 *stremmes* (42 500 acres) yielding in a favourable year 19 312 500 kg. of oil. As a matter of fact this amount is rarely reached, for the methods both of cultivation and harvesting are poor, and moreover each year about  $\frac{1}{3}$  of the crop is destroyed by disease, involving a loss of about 15 million *drachmas*. The Ministry of Agriculture has taken steps to control the olive fly which is the most serious pest. The Berlese system has this year been applied in Corfu and an excellent crop is anticipated.

There are very few oil mills of any importance in Corfu, and less than  $\frac{1}{3}$  of the crop is treated in modern factories, the remainder all going to small native mills. The result is a loss both in quality and quantity and the same is the case for the oil of the pomace.

Most of the Corfu oil is sent to the Italian Riviera where it is refined and commands a high price. A refinery should be established in Corfu itself.

Apart from the olive, the vine is also a crop of some importance, the wine being valued at 5 million *drachmas*. The quality of the wine is very high, but owing to the spread of mildew, due to the damp climate, the vine is disappearing and being replaced by hay of poor quality.

There are a fair number of fruit trees, their product being chiefly exported to Piræus. Unfortunately the citrus plants are threatened by the "maladie de Poros" (root-rot and gummosis). This is bound to spread, as the growers reproduce chiefly by layering.

There is also a certain amount of production of cereals and vegetables, the latter being exported to Piræus. Amongst these the potato takes first place, the exportation in 1921 reaching 5 million kg., of a value of 2 500 000 *drachmas*.

The cereals grown in the island are insufficient for the local consumption and importation is necessary. Those most cultivated are wheat and maize. Production could be doubled by the use of modern ploughs, chemical fertilisers, and tested seeds. Agricultural cooperation has thus a great opportunity for fruitful activity. P. C.

#### RURAL HYGIENE

362 - **Fleas and the Methods of their Control.** — I BISHOPP, F. C., Fleas and Their Control, in *Farmers' Bulletin* 897, United States Department of Agriculture, 15 pp., figs. 5. Washington 1921. — II. DELANSE, P., Au sujet d'un piège à puces, in *Bulletin de la Société de Pathologie exotique*, Vol. XV, No. 1, pp. 39-41. Paris, January 11, 1922.

I. — The author describes in a popular manner the importance of fleas as agents transmitting infectious diseases to man (bubonic plague, infantile kala-azar etc.) and the lower animals (e. g. tapeworm to dogs) and as irritating and weakening parasites. He also gives an account of their life-history and of the means of exterminating them.

Of the known species of fleas (about 500), less than a dozen are of special interest as parasites of man and lower animals; the most important are the human flea (*Pulex irritans*), the dog flea (*Cnellocephalus canis*), the cat flea (*Cnellocephalus felis*), the fowl flea (*Echidnophaga gallinaceus*), and the rat flea (*Xenopsylla cheopis*), which spreads bubonic plague.

In order to control fleas, it is necessary to remove the centres of reproduction and destroy the parasites on infested animals. If the first operation is well carried out, the second gives but little trouble.

Fleas breed in large numbers in heaps of plant and animal refuse collected in damp shady, places protected from wind and rain. Stock should not be allowed to come near human dwellings, all excrement of any kind should be removed carefully and the place where it has lain (where the flea larvae develop, sprinkled with salt and then liberally watered. The infestation of houses can be prevented by keeping no animals indoors, taking up carpets and washing the boards, first with soap and then with petroleum. All the fleas harboured by domestic animals in a house can be destroyed by washing the hosts with dilute kerosene emulsive. This is prepared by dissolving 31 gm. of ordinary soap in 1 litre of boiling water; the mixture is removed from the fire and 1 1/4 litre of kerosene is added, stirring all the time; when the compound is well emulsified, 20 litres of water are added.

Fumigating houses with sulphur dioxide or hydrocyanic acid destroys rats, fleas and all other parasitic animals; 50-60 kg. of sulphur must be burnt per 1000 cub. m. of volume. Fumigation with hydrocyanic acid must be done with great care; the technique of the operation is described in the *Farmers' Bulletin* 699, intitled "Hydrocyanic Gas against Household Insects."

After the animal hosts have been treated and the house has been thoroughly cleaned, traps may prove useful. In order to attract adult fleas at night a small lamp can be placed in a dish of water covered with a layer of kerosene. Many of the insects may be caught by leaving a cat or guinea-pig in the room all night. The animal must be thoroughly washed in the morning with the solution referred to above.

To allay the irritation produced by flea-bites a 3% solution of carbolic acid, or tincture of iodine may be used.

This bulletin is the second edition revised of the *Farmers' Bulletin* No. 683, November 8, 1915.

II. — The author has used with success a light trap similar to that suggested by BRISHOPP but with oil instead of petroleum. He remarks that the trap only acts well if the doors and windows are properly shut so that no external light can penetrate into the rooms.

F. D.

363 — **Lathyrism** (1). — VISCO, S., in *Atti della Reale Accademia dei Lincei, Quinta Serie, Rendiconti, Classe di Scienze fisiche, matematiche e naturali*, Vol. XXX, Parts 5-6, pp. 241-244; Parts 7-8, pp. 270-279; Part 9, pp. 379-384. Rome, Second Half-Year, 1921.

A series of observations made on rats fed on the flour of *Vicia Ervilia*

(1) See *R.* July 1921, No. 701; *R.* Nov. 1921, No. 1008. (Ed.)

suggested to the author the possibility that the syndrome known under the name of "lathyrism" might be due to a lack of cereals.

In fact one animal, which after an exclusive diet of vetch meal manifested a complex syndrome, was completely and fairly rapidly freed from the symptoms by being fed a commercial product containing vitamins and an infusion (made with cold water) of the bran of *Andropogon Sorghum*.

Pigeons given the seeds of *Vicia Ervilia* manifested the same syndrome of symptoms as others that had been fed solely on polished rice, that is to say, they had every appearance of suffering from avian polyneuritis (due to an avitaminosis), but were cured by being given antiberiberic vitamins.

The rats fed upon bread made from the seeds of *V. Ervilia* (percentage composition of these seeds: nitrogenous substances 23.6; nitrogen-free substances 62.74; ash 3.45; water 13.15; starch 52.90; Crude fibre 5.50; fats 1.90), lost flesh continuously until they reached the limits beyond which it was impossible for life to be sustained, for their food was not sufficient for their requirements in energy, nor did it supply them with the necessary amount of nitrogen. The results of the experiment seemed to show that the deficit in the amount of nitrogen was due to the absence in the feed of some amino-acid radicle. F. D.

364 - **Flora of Maize Flour.** — THOM, C., and LE FEVRE E. (Bureau of Chemistry, United States Department of Agriculture), in *Journal of Agricultural Research*, Vol. XXI, No. 4 pp. 179-188, bibliography of 8 works. Washington, 1921.

The authors in seeking possible causes for the well-recognised instability of maize meal, have found by means of cultures that many moulds and bacteria are generally present. The following species of moulds were found to be characteristic in many series of cultures: *Fusarium* sp., *Aspergillus repens*, *A. flavus*, *A. tamari*, *A. niger*, *Citromyces* (or *Penicillium* section *Citromyces*) sp., *Penicillium oxalicum*, *P. luteum* (several varieties), *Mucor*, sp. *Rhizopus nigricans* and *Syncephalastrum* sp. together with various yeasts and yeast-like fungi. Among bacterial groups, the colon-aerogenes group and lacto-bacilli were most abundant in fresh meal. Aerobic spore-formers and micrococci were always present and persisted in the stored product.

Within the range of composition found in the meals of commerce no bacterial activity was detected. Only one grade of unbolted meal showed signs of mould development below 13 % of moisture. Above 13 % of moisture, *Aspergillus repens* began to be an active agent of spoilage up to between 13 and 15 % of moisture, according to the form of milling practised. Several other species of mould are active in meal containing 16 % moisture, and numerous forms, including some bacteria, develop when 18 to 20 % of moisture is found.

Many samples of maize were extensively infected with *Fusarium*, *Diplodia*, *Aspergillus repens* or *Penicillium*, especially in the germinal area and in the tip of the kernel. These portions of the kernel are remov-

ed in varying degrees by different milling systems. The bolted meals examined showed a corresponding reduction in the number of viable organisms as shown by cultures.

F. D.

365 - **Suggestions for the Organisation of Stations for Agricultural Research in France and the French Colonies.** — *Revue de Botanique appliquée et d'Agriculture Coloniale* Year II, *Bulletin* No. 5, pp. 25-26. Paris, January 30, 1922.

AGRICULTURAL  
EXPERIMENTATION

In the course of its last annual Congress August 1921, the "Association française pour l'Avancement des Sciences" being convinced that : 1) the development of agriculture in France and its colonies should be one of the chief factors of the economic revival of the country ; 2) that scientific methods should be applied to the improvement of useful plants in France and its Colonies ; 3) that it is a proper function of the State to carry out the long experiments and studies necessary for the attainment of practical results, made the following recommendations :

a) That the already existing Experiment Station should be maintained and developed, and that there should be created in France and the Colonies, new specialised Stations for the study of the chief crops to be developed ;

b) That the public establishments engaged in plant acclimatisation or improvement that are already in existence, or that shall be created in the future (Agricultural Experiment Stations, Colonial Scientific Institutes), should be provided with adequate staffs and material and endowed with the means necessary for the continuation of their researches ;

c) That every Experiment Station dependent upon a State Service should draw up annually, before March 31, a report giving an account of the experiments made and the results obtained during the preceding year.

d) That the results obtained should be widely circulated ; that popular pamphlets dealing with the chief crops of the mother country and the colonies should be edited by specialists, printed in large numbers and distributed in the schools and among agriculturists and colonists ; finally, that large numbers of the seeds, cuttings or grafts of acclimatised or improved plants should be placed at the disposal of the public.

G. A. B.

366 - **Agricultural Experiment Stations in Czecho-Slovakia.** — 1. Agricultural Experiment Stations, *Bulletin of the Ministry of Agriculture of the Republic of Czecho-Slovakia*, Year III, No 1, p. 6. Prague, January 1, 1922 -- The Budget of the Ministry of Agriculture (1922). *Ibidem* -- III The Sale of the Stock of Chemical Fertilisers at the Ministry of Agriculture, *Ibid* p. 5.

I. — In Bohemia, Moravia and Silesia, there are 25 Experiment Stations devoted to or very closely connected with Agriculture. They are supported either by the State or by autonomous Societies. There are in addition some private Stations.

Most of the Stations have their headquarters in Prague, and this applies to the following which are subordinate to the Chamber of Agriculture : the Physiological Station, Experiment Station of Chemical Fer-

tilisers, Station of Agricultural Bacteriology, Institute of the Dairy Industry, Experiment Station for Testing Agricultural Machines, Soils Bureau, Station of Agricultural Chemistry, Institute of Agricultural Book-keeping, and the Seed Control Station. There is a large Provincial Agricultural Experiment Station at Brno in Moravia, which had a budget of 1 187 600 crowns in 1922; it is supported by an Administrative Committee (an Autonomous Body), and includes several sections. When its organisation is complete, this Experiment Station will be one of the largest in the world. The above Committee also supports an Institute for Plant Improvement, at Pířerov (Moravia).

Experiment Stations are also attached to most of the Agricultural Colleges, as for instance at Tábor, to which are annexed; the Agricultural Experiment Station, the Machine-Testing Station, the Station for the Cultivation of Forage Plants and the Phytopathological Station — at Roudnice; the Station of Agricultural Chemistry, and the Phytopathological Station — at Plzeň; the Dairy Industry Station — at Chrudim; the Plant Improvement Station — at Kroměříř, the Dairy Industry Station — at Prague, the Distillery Industry Institute and the Scientific Brewery Institutes. These two last Stations are annexed to special private schools, while a Carpentry Institute forms parts of the Technical College of Prague, etc.

In Slovakia, the Government has instituted Stations at Bratislava, Košice and Stávnice.

Arrangements are being made for the organisation of other Experimental Stations for the different branches of Agriculture (pisciculture, aviculture, silviculture, improvement of cattle breeds). At the present time, the Nēm-Brod Potato Cultivators' Union is engaged in organising, with the assistance of the Ministry of Agriculture, a special Station on the Valečov estate.

All the Czech Experiment Stations are united in a Federation having its head-quarters in Prague.

In conclusion, there are the private Experiment Stations — the Sugar Industry Station in Prague — the Dobruřice—Seměice Station for the Improvement of Seeds especially those of the sugar-beet, the Joint Stock Company "Thurn-Taxis" which deals with the agriculturists of the different districts of Bohemia, and exports a considerable quantity of sugar-beet seed — the Stations of Chlumeck (Nolč-Dreger), Nalžov, etc.

II and III. — The Ministry of Agriculture has included in its 1922 Budget 18 514 427 crowns for Experiment Stations, and 31 399 941 crowns for Primary and Secondary Schools of Agriculture; the support of the Agricultural Colleges devolves upon the Ministry of Education. In addition the profits from the stocks of chemical fertilisers on sale at the Ministry of Agriculture will be employed for the foundation of an Experimental Institute of Agriculture and Silviculture, the Agricultural Museum and other objects of importance to agriculture.

G. A. B.

367 - **The Standardisation of Field Experiments.** — WIANCKO, A. T., ARNY, A. C., SALMON, S. C. (Committee on Standardisation of Field Experiments), in *Journal of the American Society of Agronomy*, Vol. XIII, No. 3, pp. 368-374, bibliography Lancaster, Pa., January 28, 1922.

The Committee appointed by the American Society of Agronomy for standardising the methods of conducting field experiments has for many years been making a careful study of the question. Information concerning the practice of the majority of the Experiment Station workers in the United States has been collected. With the data at hand, the Committee now feels that the Society of Agronomy should begin to define and adopt certain standards for locating, laying out and conducting the ordinary kinds of field experiment.

The great variety of conditions under which field experimental work must be done makes it impossible in certain respects to lay down any but very general rules. Some guiding principles can, however, be fixed in order to make such work more uniform and the results more accurate. The chief points in the authors' paper may be summarised as follows:

**RECOMMENDED STANDARDS FOR FIELD PLOT EXPERIMENTS IN SOIL FERTILITY.** In each locality, one type only of soil should be represented in any one experiment. It is therefore necessary before beginning the experiments to ascertain the uniform character of the piece of land chosen. Topographically it should be reasonably level and slope in one direction only; otherwise special precautions must be taken to prevent soil-washing. When artificial drainage is required the drains should be so arranged as to influence all plots alike. Where irrigation is practised, provision must be made to water all plots at the same time and at the same rate. While the size of the plots must often be governed by the number of plots required for the particular experiment and the amount of land available, twentieth-acre to tenth-acre plots will usually be found the best where horse and machine labour are to be used. Long, narrow plots laid out crosswise to the greatest soil variation are preferable to square or oblong plots as these are more likely to show important differences in soil fertility. The four corners of any series of plots should be indicated by permanent marks. Check plots receiving a uniform soil treatment to maintain them in a reasonable state of productivity should be regularly distributed throughout the series. At least every fourth plot, preferably every third, should be such a check plot in each series, and one or more untreated plots should also be included. The complete series of treatments should be repeated as many times as there are crops in the rotation employed. In all soil fertility experiments the plots must be separated by untreated interspaces at least 3 ft. in width, and the entire series of plots should be surrounded by regularly planted side and end border strips to be cut off at harvest time. Only high quality acclimatised seed of standard variety should be used and it must be uniformly treated. The calculation of increases due to treatment should be based on the assumption that the difference between the two checks is uniformly progressive. All cultural operations, except ploughing, should be conducted lengthwise of the plots.

to prevent all possibility of moving soil or fertiliser from one plot to another. Ploughing should however usually be crosswise of the plot, and hill-planted crops may be cross-cultivated. Yields ought usually to be determined by harvesting and weighing the produce of the entire plot; the produce must be uniformly dried before weighing. Should this have been omitted, the moisture content ought to be determined and proper corrections made before recording the weights.

**RECOMMENDED STANDARDS FOR FIELD EXPERIMENTS WITH FARM CROPS.** — All seeds used for planting must be of known vitality and free from mixture, weed-seeds and contamination or infection by disease. The soil for experimental plots ought to be as nearly as possible of the type prevailing in the area where the data from the crops grown on them are to be applied. As a rule, relatively long and narrow plots are to be preferred, but they must be sufficiently wide to allow for the removal of border-rows (2 in the case of cereals and 1 for intertilled crops). Practically, 5 ft. or more is a good width for plots planted with small grains and forage crops; in the case of intertilled crops, sufficient width must be allowed for 4 rows. Adequate repetition of varieties or treatments renders unnecessary the use of check plots. In fact the number of years a test is continued together with the number of plots devoted to any one variety or treatment, and the size of the plots are in definite relation to the probable error for any particular test. When single plots of varieties or treatments are used, the probable error will average lower on tenth acre plots than on plots of smaller size. The increase in probable error is however relatively small when the decided reduction in size of the plots is considered. By repeating varieties or treatments a sufficient number of times on regularly distributed plots of any size adapted to the purpose of the experiment, the probable error for the test may be reduced to any point considered necessary. For ordinary conditions, from 2 to 5 repetitions are recommended, 2 plots of any variety or treatment, continued through 4 years, or 3 plots continued for 3 years, should be regarded as the minimum. New varieties and cultural methods or treatments materially different from those in common usage should not be recommended for general use, unless supported by at least 3 years of repeated and carefully conducted experiments within the area for which the recommendations are made.

To the article are appended additions to the bibliography published in 3 previous issues of the Journal of the American Society of Agronomy.

368 — **Experimentation and Yield of Cotton, Sugar Cane, Bay Trees, and Other Crops in Montserrat, West Indies.** — *Imperial Department of Agriculture for the West Indies, Report on the Agricultural Department, Montserrat 1919-20, pp 1-40 + tables. Barbados, 1921*

**I. COTTON.** — As the result of successful cultivation of the strain H23 from 1916-19, further tests were made which proved the undoubted superiority of this strain as regards cropping qualities. This is evident

also from the comparative data referring also to strains H9 and D1. Special note is made of the particularly good results obtained with type H23-2-13 which gave a yield at the rate of 921 lb. per acre. Special work was undertaken to analyse the characters of the individuals of this strain for the purpose of securing mother plants as starting points for a new race with an efficiency above the average of the type. Data relative to the lint length, seed weight, lint index, lint and seed-cotton per boll, percentage of lint, bolls per lb., seed cotton and average number of loculi per boll are given.

New selections are also being made from the H9 strain and several new crosses have given interesting results.

Comparative trials with St-Vincent, Montserrat and St. Kitts cottons are reported and it is noted that the types were placed in the above mentioned order of merit after ginning and forwarding to the factory for spinning tests.

From the 3 200 acres planted in cotton the total yield amounted to 548 334 lb. of lint, i. e. an average of 171 lb. per acre. The practice largely followed was to leave two cotton plants per hill instead of one, and as the results proved most satisfactory, this method is most likely to be followed in the future.

A certain amount of the cotton seed employed, showed lack of viability, and it is advised that as non-viability is due to fermentation or heating of seed-cotton in bulk after picking, seeds which are to be reserved for sowing should be exposed for a longer time to the sun. Trials have shown that if exposed for one week, seeds have proved as viable as when brought from the field.

The type of cotton now cultivated appears to be remarkably free from attacks of bacterial disease in its various forms, and where the second crops were harvested early, the damage from cotton stainers (*Dysdercus* spp. and *Oxycarenus* spp.) was negligible; late planted areas however suffered badly from attack.

II. — SUGAR CANE. — Comparative trials were made with 22 varieties of cane. Samples of each variety were crushed and the juice, preserved with formalin, was sent for analysis to the Government Laboratory at Antigua. The field results together with the results of chemical examination are given in tabular form. First on the list as regards sucrose value comes the B.H10 (12) with an average return of cane per acre for 2 years of 31.25 tons, giving the average amount of sucrose per acre as 8 180 lb. The next, namely Scaly Seedling gave a somewhat higher average for canes, viz. 33.6 tons, but a lower sucrose production, viz. 7 370 lb. These two varieties stand first also in the records made as regards the ratoon canes. In 1920 the first mentioned gave 18.1 tons of cane per acre and the second 11.5 tons.

The success obtained with this new variety B. H. 10 (12) confirms the results obtained in other West Indian islands.

III — BAY TREES (*Pimenta acris*) (1). — Reaping of the leaves

(1) Reproduced in *Agricultural News*, Vol. XX, No. 503, p. 246, London, Aug. 6, 1921 (Fd.)

for distillation has been in progress since 1911 and has continued systematically up to the present time (*West Indian Bulletin*, Vol. XV, pp. 176-197). During the 1919-20 season 52 distillations were made and samples of oil from each distillation (100 cc) were submitted to Antigua for examination. The average yield of oil per 100 lb. of green leaves was 17.3 oz.; the phenol content varied from 48 to 63 %. It is interesting to note the rise in yield from 1368 lb. green leaves in 1911 to 8020 lb. in 1919 and the rise in value per acre from £7 to £60. Frequent distillations were made throughout the year to ascertain the most favourable season for carrying out these operations. Details may be found in the Annual Reports of the Botanic Station.

The best average results as regards oil yield were obtained between January and July, but this has been attributed to the dry weather prevailing at this season.

As regards the quality of the oil as indicated by the specific gravity and the phenol content between which a certain correlation is evident, the best results were obtained between March and October.

In consideration of the fact that only fully developed leaves have been used for distillation, nothing has been attempted when the trees were making new growth. The bay trees on the experiment plot are so treated that collections of leaves can be made from ground level, the trees being sawn off and the leaves stripped later. It has been found satisfactory to cut down the trees once a year.

Further investigations must be made as to the right conditions of the leaves when collected as results have been disappointing in cases when very old leaves have been collected.

IV. MINOR CROPS: 1. *Yams* (*Dioscorea* spp.) — Experiments were made to ascertain the advantage of staking the haulms, and results showed an average gain of nearly 100 % over unstaked plants. The heaviest cropper on the average of 3 years' results proved to be the variety Antigua Lisbon with an average yield per acre of 23 267 lb.; this variety is also of good cooking quality.

2. *Sweet potatoes*. -- Data are given for the average results of, the 16 varieties tested. The variety Red Bourbon gave the highest yield the average yield per acre being 13 258 lb.

3. *Datura Metel*. — Dried leaves and ripe seeds of this local plant have been submitted for examination to the Imperial Institute, London to determine the commercial value of the product as a source of scopolomine. Manufacturers reported that satisfactory results were obtained with the leaves and on treating 250 lb. a yield of 0.518 % of crystallised hyoscyamine and 0.0542 % of hyoscine was given. The proportion of hyoscyamine and scopolomine in the seeds is evidently variable, approximately in the ratio 8 : 1 and this appears to be the first recorded instance in which the hyoscyamine was the predominating alkaloid to such a pronounced degree. The commercial value of the seed is, however, of a doubtful nature, as other available materials contain larger proportions of these alkaloids.

4. *Momordica cochinchinensis*. — A limited number of plants were raised for the first time, and the seeds obtained were sent to Antigua for analysis of the oil content. The seed was composed of shell 38.1 % and kernels 61.9 %; the former contained 0.80 % fat and the latter 52.06 %. The fat obtained was of the consistency of castor oil.

5. *Wind-break plants*. — The results obtained with the following plants are reported. White cedar (*Tecoja Leucoxydon*), Machineel (*Hippomane Mancinella*), Spanish ash or oak (*Inga laurina*), Galba (*Calophyllum Calaba*), Angelin (*Andira inermis*), Bread-and-cheese (*Pithecolobium Unguis-cati*) and *Pimenta acris*

AGRICULTURAL  
INSTITUTIONS

The object of the establishment of the West Indian Agricultural College is to promote the study of agriculture in the Tropics and to provide instruction in the cultivation and marketing of tropical products of every kind, including sugar, and its by-products, rum, molasses, cacao, coffee, cotton, coconuts, rice, citrus fruits, etc, dye weeds and all vegetables, mineral and marine products of the British West Indies (including British Guiana and British Honduras) to make full provision for research work and for the training of scientific investigators in matters relating to tropical agriculture, with a view to creating a body of expert agriculturists capable of founding, establishing and maintaining other colleges, etc., of a similar nature

Further information as regards the development of the College, the various ways in which West Indian natives are likely to benefit etc will be forthcoming.

## CROPS AND CULTIVATION

370 — **Studies on the Reduced Yield of the Chief Farm Crops, especially as caused by Adverse Weather Conditions in the United States.** — VALGREN, V N, in *U S Dep. part of Agric, Bull. No 1013, Office of Farm Management Farm Economics*, pp 123 Washington, January 1922.

AGRICULTURAL  
METEOROLOGY

**THE FREQUENCY AND INTENSITY OF ADVERSE WEATHER CONDITIONS** — It is well known that the great variations observed in the yields of cultivated plants are due to unfavourable weather conditions, plant diseases and animal pests. In order to be able to estimate the loss entailed, the author lays stress at the outset on the necessity for a clear definition of the terms "loss" or "damage", when used in connection with crops. The expression "crop damage" should be applied to a loss caused by the inferiority of a crop yield in a given region to the maximum owing to unfavourable weather conditions, whereas the term "financial loss" ought to be reserved for cases where the loss was not only crop damage, or a diminution in yield, but a financial loss on the season's operations.

Let it be assumed that 3 farmers (X, Y and Z) are engaged during a given year in producing wheat by dry-farming methods in three semi-arid regions of the West, and that the average yield in each of these regions for the last 20 years has been 8 bushels an acre which would be sufficient to cover all proper charges. In exceptional years, 35 bushel yields have been harvested on each of these farms.

If in the district where X works average conditions prevailed throughout the year and he actually reaped an 8 bushel crop he has had neither profit nor loss, though his prospects were early reduced by natural causes. If the climatic conditions had been entirely favourable, he would have reaped 35 bushels per acre. Where Z was farming, all the conditions remained highly favourable until within two weeks of harvest time, when a hailstorm destroyed 60 per cent of his crop, which gave an actual yield of 14 bushels per acre. In this case there is no financial loss, the farmer realised a profit in as much as 8 bushels per acre covers all charges.

On the other hand the crop was undoubtedly damaged by the hail, and if he had insured it he would have been entitled to an indemnity equivalent to 60 % of his insurance per acre.

Finally Y, who because of frosts and drought reaped no harvest whatsoever suffered, a loss equivalent to his entire expenditure of labour and capital chargeable to the year's operations, and this is a case of true "loss."

Even after this attempt at clear definition one of the terms "crop damage" still retains a vagueness which it seems impossible entirely to remove. It implies that the best crop yet harvested was perfect having suffered no damage of any kind, whereas it may well be questioned if any such crop has as yet been reaped. It is also obviously impracticable to arrive at any figures representing the "crop damage" for a larger area, or for the country as a whole.

In order to obviate these difficulties and to make it possible to work out approximate figures for the amount of crop damage from various causes, the United States Department of Agriculture has arbitrarily assumed that a crop exceeding by 10 % the normal yield is a perfect crop. The normal yield is defined as the yield which has been observed by the crop-reporter actually to occur over extended areas in the ratios used in reporting on crop prospects as well as crop damages from different causes.

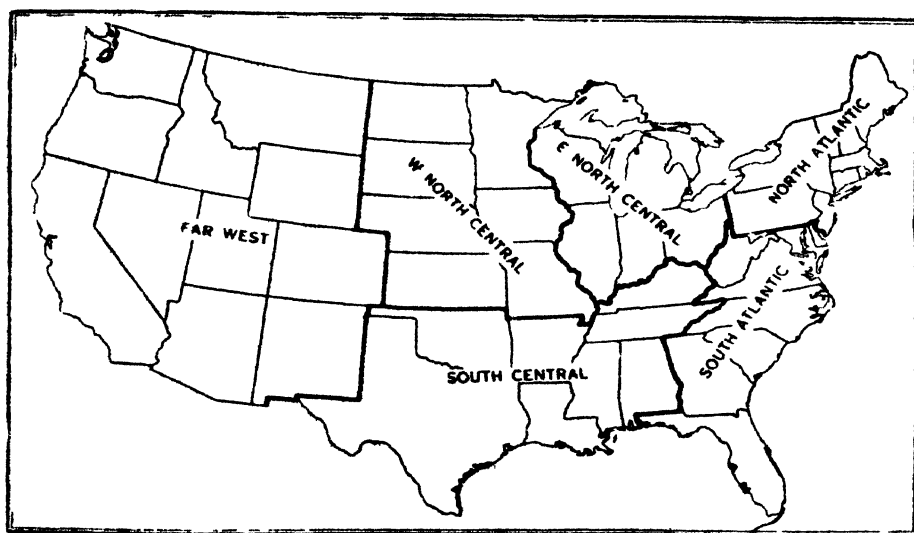

The difference between a perfect or "no damage" yield and the actual yield, is the measure of "total crop damage." About 12 years ago the United States Department of Agriculture began to require of its thousands of crop reporters in all parts of the country estimates of the percentage of damage caused by adverse weather conditions. The returns were to be expressed in % of the normal crop and calculated according to the standard indicated above.

The crops covered were maize, wheat, oats, rice, barley, flaxseed, potatoes, tobacco, hay and cotton. Table I gives the data relating to

the 3 leading crops wheat, maize and cotton. The figures represent the average annual damage during the decade 1909 to 1918 in the 6 great geographical divisions of the United States: North Atlantic, South Atlantic, East North Central, West North Central, South Central and Far West (See figure)

The purpose of Table I is to bring out the relative importance of the different risks or causes of damage with reference to each of the crops enumerated for the country as a whole as well as for the various geographical divisions. Thus in the case of maize, deficient moisture was the most dangerous risk, not only for the country as a whole, but also for all the geographical divisions, after drought come excessive moisture, frosts, insect pests and hot winds.

Geographical Divisions of the United States referred to in Tables I and II

The figures in Table II represent, not only the relative severity of the risks or causes of damage, in each case, but also the importance from the point of view of the acreage or volume of the given crop in the division or the country as a whole.

It is evident that the data given in the two Tables cannot always correspond. Thus according to Table I an average of 112% of the maize crop was lost annually through hail, which was a higher percentage of hail damage than occurred in any of the other 5 divisions, but owing to the relative unimportance of the maize crop in the Far West, the total hail damage was only 300 000 bushels.

On examining Table II it is seen that deficient moisture is again the chief cause of crop damage for each of the crops mentioned, excessive moisture, however, ranks second for maize, oats, rice, tobacco and hay.

TABLE I. — *Average Annual Crop Damage (in % of Normal Yield) by Geographic Divisions for Decade 1909-1918.*

In the case of wheat on the other hand plant diseases are the second most important cause of damage with insect pests third; the same holds good for potatoes. In the case of barley, hot winds come second as a source of damage, while cotton insect pests occasion almost as much damage on the average as deficient moisture.

Expressed in terms of dollars, the average annual crop damage during the 11-year period was 2620 million dollars, with a minimum of 2054 million dollars in 1912 and a maximum of nearly 3066 million dollars in 1918.

It must however always be remembered that these figures do not represent the actual monetary loss to farmers, but loss due to adverse weather conditions and already taken into account in judging of the expediency of the agricultural undertakings.

**ELIMINATION OR REDUCTION OF RISKS. — Self-Insurance —** One of the best ways of avoiding damage due to bad weather is to avoid monoculture which exposes the farmer to the risk of losing the results of an entire year's work from a single catastrophe. If he invests part of his capital and labour in live stock or in a variety of crops, it is highly improbable that all his sources of revenue or branches of activity will be affected in one and the same year. Many bankers in regions where a one-crop system has prevailed now insist as a condition of granting a loan to the farmer that he shall use a safe-cropping system.

Another way in which the farmer can reduce the risks of crop damage caused by weather is by making a study of the climatic conditions of the region and adjusting the planting, and hence the growing seasons of his crops to the weather. At Grand Rapids, Mich, for instance, the average date of the last killing frost in the spring is May 11, while the average date of the first killing frost in the autumn is about Oct. 8. This gives an average of 150 days without frost. Weather Bureau records further indicate that 5 times in 20 years the date of the last destructive frost in the spring has been 10 or more days later than the average, and that 4 times in 20 years, the date of the first killing frost in the autumn has been 10 or more days earlier than the average. The period absolutely free from severe frosts is thus reduced to a maximum of 130 days. The injurious effects of frosts could be reduced to a considerable extent, if the farmer adjusted his dates of planting to the local climatic conditions and selected the varieties of his seed with due regard to these conditions.

What has been said about frost applies also to drought, excessive moisture and other climatic dangers.

**Contracts of Insurance. —** Tables I and II give a general idea of the risks and losses to which the producer of crops is exposed independently of his skill or forethought. Even after many of these risks have been reduced or eliminated by the principles of self-insurance already mentioned there remains a large element of risk that can only be adequately met by a reliable contract for indemnity, or in other words by insuring the crop. In 1917, the first attempts at crop insurance were made by three joint-stock fire-insurance companies in Montana, North Dakota and South Dakota. The insurance covered all the risks to which

crops are subject, with the exception of fire, floods, "winter-kill" and neglect. Under this insurance, the farmer insures his wheat at 7 dollars per acre. In the case of partial loss, the Company paid for wheat 1 dollar; flax 1.75 dollars; rye 70 cents; and oats, barley and spelt 50 cents a bushel. These first attempts at general crop insurance proved rather disastrous for the Companies that undertook them, owing in part to the severe drought that occurred in large sections of the States named.

In 1920 new crop insurance policies were issued guaranteeing the farmer against frost, "winterkill", flood and drought, damage due to fire, hail, wind, tornado and failure of seed to germinate being excluded. Unlike the 1917 contracts the policy does not place a fixed value on the grain harvested, but provides instead for a valuation on the basis of market price at the time the contract is signed. The Companies were again severely hit in this case because of an unexpectedly heavy fall in prices.

In a third and still more recent type of policy, the amount of insurance to the acre is based on a certain percentage of the average yield during the past 5-year period, this being translated into dollars by assigning to it a value based in the price prevailing during this period.

Thus a farmer, who had averaged during the past 5 years 48 bushels of maize per acre, may be offered insurance for an amount equal to the value of about 36 bushels at the average price for maize during the past 5 years. This form of insurance is certainly more favourable to the Companies than either of the two preceding forms from which it differs in the following important points:

- 1) In the case of total destruction of the insured crops, the Company agrees to pay 75 % of the cost of the field operations actually performed, such indemnity not to exceed 75 % of the total insurance.

- 2) The indemnity shall in no case exceed the actual value of the lost produce.

PRINCIPLES OF CROP INSURANCE. — The author criticises the different forms of insurance and after considering the question from different points of view, summarises his conclusions as follows:

- 1) The insurance must cover only such crop damage as will result in serious financial loss to the farmer. For establishing the reasonable amount of insurance per acre, the average yield and price for a series of past years is perhaps the best basis. Further the acreage of a given crop, if not the entire farm, must be insured as a single unit and adjustment made on the basis of average yield of such acreage. The total loss of crop on one or two acres out of a hundred is not a serious loss, if the acreage as a whole gives average returns.

- 2) The insurance must cover any and all risks which are beyond the farmer's control. Insurance which protects against certain risks and leaves the insured exposed to total loss from others beyond his control is not an effective crop insurance.

- 3) In no case must the insurance protect against loss from carelessness or negligence on the part of the insured. Such protection is

contrary to sound principle and inimical to the best interests, not only of the company, but also of the insured and of the public in general.

4) The premium or cost of insurance must bear a reasonable relation-ship to the value of the protection that it purchases; the expenses item in the expenditures of the insurance organisation should absorb only a small part of the premiums collected, the profits of the Company must be moderate and the bulk of the premiums must be available for the payment of current claims, or accumulated to form a reserve fund for payments in respect of future losses.

5) The method of estimating loss must be such that the insured will receive indemnity for crop damage in such sums as he is led to expect from the figures indicating the amount of insurance per acre.

6) Provision should be made for an early valuation in case of the total failure of an insured crop, or such an approximation to failure that it would not pay to mature and harvest the crop. In all cases, the indemnity should not exceed the value of the labour and other costs, including rental that have been actually lost.

7) All claims involving only partial damage should as far as possible be left until after the crop has been harvested and made ready for market so that the quantity and grade can be determined. G A

371 - **The Control of the Effects of Wind by Means of Plant Wind-Breaks in Tropical America.** — *The Journal of the Board of Agriculture of British Guiana*, Vol. XV, No. 1, pp. 25-26. Demerara, January 1922.

Wind-breaks not only protect plantations from the mechanical action of strong air currents, but also against excessive evaporation and transpiration of the soil and plants, phenomena which are promoted and increased by wind.

The species recommended for wind-breaks in the Antilles and Guiana are those belonging to the genera *Aralia* and *Hibiscus* — *Calophyllum Calaba* ("Galba") — *Mammea americana* — *Eugenia caryophyllata* (clove-plant) — *Swietenia macrophylla* (Honduras Mahogany) — *Mangifera indica* (mango) — *Cinnamomum Camphora* (Camphor) — *Eugenia malaccensis* (jambosa of Malacca).

All these plants make a thick and very high screen, and some of them, such as the camphor tree and clove plant, have also an economic value, while others (*Eugenia malaccensis*, *Mangifera indica*, *Mammea americana*) bear edible fruits. G A.

372 - **Effect of the Length of Day on the Differentiation of Characters of certain Lucerne Varieties and the Possibility of Utilising this Phenomenon as a practical Means of Identification.** — OAKLEY, R. A., and WESTOVER, H. L., in *Journal of Agricultural Research*, Vol. XXI, No. 8, pp. 599-607, pl. 111-121. Washington, July 1921.

When the seed of Peruvian, common Kansas-grown, Grimm and Turkestan lucerne is sown in the early autumn in the approximate lat-

itude of Washington, the seedlings at an early stage develop characteristics that make it easy to distinguish the different varieties from one another

Peruvian lucerne produces erect, sparsely branched seedlings of greater height than the other varieties. They are also more nearly uniform. The Kansas seedlings are very similar to those of the Peruvian variety, but are not nearly so tall and show a greater tendency to send out basal branches.

The Grimm seedlings are still shorter, more branched and less erect. They also showed more variation.

*Medicago falcata* has yellow flowers, very short stems and a rosette-like habit.

Seedlings from spring sowings at Washington or further north, do not develop differences that are apparent to the untrained eye.

At first it was thought that the temperature of the autumn days was responsible for the striking differences shown by the lucerne seedlings, and it was only after the publication of the results of GARNER and ALIARD's work on photoperiodicity that it was thought advisable to make a test experiment for the purpose of determining whether the difference between the autumn and spring seedlings was due to the length of the solar day rather than to temperature.

Three series of small plots were sown on January 20, 1921 with the seed of Peruvian, Kansas, Grimm and Turkistan lucernes, and also with *Medicago falcata*. One series was left under normal conditions. In the case of the second the duration of the day was shortened by placing a light excluding box over the plot from 4 p. m. to 9 a. m. The duration of the light was lengthened for the third series by turning on an incandescent light at dusk and turning it off at 11 p. m.

The seedlings grown under the normal and shortened day behaved essentially like those from sowings made in the autumn. In height the varieties are ranged as follows:

1) Peruvian, 2) Kansas, 3) Grimm, 4) Turkistan, 5) *M. falcata*.

The following are the respective heights of the seedlings as measured on March 3, 1921:

First Series: 1)  $3\frac{2}{3}$  in., 2)  $3\frac{1}{2}$  in.,  $2\frac{1}{2}$  in., 3) 4) 2 in., 5)  $1\frac{1}{4}$  in.

Second Series: 1) 3 in., 2)  $2\frac{1}{2}$  in., 3) 2 in., 4)  $1\frac{2}{3}$  in., 5) 1 in.

On the other hand there are striking differences in the third series, but the behaviour of the varieties is practically the opposite from what it was in series 1 and 2. In fact at the end of the first month, the seedlings of *M. Falcata* and Grimm exceeded in height those of the Peruvian and Kansas varieties. They were also erect and unbranched. Their height in inches was as follows: Peruvian 5, Kansas  $4\frac{1}{2}$ , Grimm  $4\frac{4}{5}$ , Turkistan  $4\frac{4}{5}$ , *M. falcata* 5. From these experiments it is clear that it is the day-night relation of lucernes and not their reaction to temperature that causes the development of marked differences between the seedlings of the varieties of lucerne when the seed is sown at certain times of the year.

By properly controlling the duration of lighting, it is possible by this method, and with little trouble or expense to identify the various lots of seed sent for certification

G A

373 **Influence of Light and Temperature on Sexual Expression in Hemp.** — SCHAFFNER, J. R., in *The Botanical Gazette*, Vol. LXXI, No. 3, 197-219, fig. 1, 11 pl. Chicago, Illinois, March 1921

This study was originally undertaken by the author to determine what influence the environment might have on the sex ratio between male and female flowers in hemp (*Cannabis sativa* L.)

**CHARACTERS OF FEMALE PLANT** — Well developed root system; robust stem not so tall as in the male plant; broad, flat crown of leaves; large leaf-blades with more numerous leaflets (5 or more); terminal inflorescence usually leafy, petioles long and robust, female flowers with no vestigial stamens, weight at the beginning of the flowering period nearly twice as great as that of the male plant at the same age, longer growing period

**CHARACTERS OF MALE PLANT** — Small root system, slender spindling habit and greater height due to the very rapid elongation of the internodes just before anthesis, small leaf-blades with fewer leaflets, shorter and more slender petioles, terminal inflorescences with few or no leaves; male flowers with 3-6 sepals (usually 4 or 5), with no vestige of gynoecium, weight about half that of female plant at time of anthesis, much shorter life than that of female plant

Hemp planted in spring in the open, under normal conditions produced pure male and pure female plants without confusion of sexuality in the ratio of about 1:1, with deviations in either direction for various plots

On the other hand, if the sowing was made in winter, in the greenhouse or on shallow benches with low light intensity, there was great confusion in sexual expression. Abundant irregularities were produced such as stamens with normal stigmas, and structures partly male and partly female, as well as more typically bisporangiate flowers and flowers typical of the opposite sexual state (see Table)

Plot No	Female Plants		Male Plants	
	Pure	Mixed	Pure	Mixed
4	60	54	75	57
5	23	30	19	20
8	25	19	12	29
9	19	24	5	29
10	7	16	13	17
11	2	16	2	11
12	4	32	4	13
13	17	26	9	22
14	20	37	5	18
Totals . . .	167	254	144	216

The percentage of intermediate individuals was much higher in the plantings of the winter of 1919-1920 than in those of the winter 1918-1919. This is apparently due to the fact that in 1919-1920, the plants were sown later (in November and December instead of in January and February), and therefore received the minimum of light. The effect of the physical environment is thus already beginning to show itself in the ratio of sexual expression.

The most interesting point is however the sexual reversion which took place to a large extent; both male and female plants showed reversal in their growing period to the opposite sexual state. In extreme cases over 88 % of the female plants became male, and 80 % of the male plants were transformed into females.

The female plants that are partly intermediate from the first, or afterwards become male, produce normal seed, until the transformation takes place. This reversal takes place at a very advanced stage of development (immediately before or after anthesis until extreme old age), therefore the plant retains its female characters with the sole exception of the flowers.

In sex reversal, some individuals produce only imperfect stamens with defective pollen and indehiscent anthers, while others produce quite normal male flowers.

The reversal is usually less complete in the male than in the female flowers probably because with the males, senility sets in soon after the beginning of anthesis, whereas in the case of the females, there is a long active period after anthesis which permits the environmental factors to have full effect in the growing vegetative tissues.

Plots 11 and 12 shewed the greatest degree of reversal of sex; these plots were situated on the north side of the greenhouse where they received the minimum of light and were kept at a lower temperature.

A few special cases were carefully studied in relation to the progressive change in sexual expression. A certain number of normal females produced 2 or 3 normal seeds and then gradually changed to the staminate condition, until finally they bore male flowers only.

The decided sexual dimorphism exhibited by the sporophyte of the hemp is not due to some homozygous or heterozygous condition, but depends upon the metabolic state of the male and female cells, which can be influenced, especially as regards sex expression, by external agents, particularly by light and temperature.

G. A.

374 - **On Average Soil Temperature.** — EREDIA F, in *La Meteorologia pratica*, Year II, No. 2, pp. 41-46, fig. 1. Montecassino, 1921.

SOIL PHYSICS

EREDIA states, as a result of his study of the determinations made at the "Osservatorio astrofisico" at Catania in the first place, and also of the observations of other authors, that the annual variation in soil temperature may be expressed by a logarithmic equation. Although in temperate regions the depth to which this variation extends is consider-

able, being certainly never less than 10 metres, in tropical countries, as BOUSSINGAULT had already shewn, the upper layers only are thus affected.

Determinations of soil temperature are of the greatest importance, as they furnish data that are very useful especially in botanical research, if taken to the depth of 1 m. Even if made at different times they are of value when coordinated with other observations of the same character, provided that the temperature of the air is determined at the same time as the soil-thermometer is read (1) G A B.

**375 - Soil Temperature and its Effects on the Development of the Nodules of Leguminosae. —** Seen No. 394 of this Review.

**376 - Preparation of Soil Solution. —** GRILVES, I F, and HIRST, C F (Department of Chemistry, Utah Agricultural Experiment Station, Logan, Utah) in *The Journal of Agricultural and Linnæan Chemistry*, Vol XIV, No 3, pp 224-226, bibliography of 23 works Washington, March 1, 1922

In the investigation of 'alkali soils' it is often difficult to obtain a clear filtrate, because in the watery extract the degree of dispersion of the colloidal disperse phase is so great, and in such a stable form, that the solution may be kept for years without flocculation. The particles of such a phase are so small that it is impossible to separate them by ordinary filtration. It is imperative however that the soil extract should be free from colloidal particles, for coloured colloids interfere with the sharpness of the final reaction in colorimetric and some volumetric reactions, and where the colloid is of a protein nature, subsequent reduction may liberate nitrogen or ammonia, which in the final reaction may be interpreted as nitric nitrogen. Further the colloids may actually combine with one or more of the reagents and produce erroneous results.

The ideal method of obtaining a clear aqueous solution would be one which yielded a clear solution without flocculation. This would necessitate the addition of a flocculent which is rapid in action and will remove only a minimum quantity of the soluble salts from the solution without interfering with the sensitiveness of the method. The results of a comparison of the different agents that can be used for this purpose shewed that clear soil extracts may be obtained by adding to 100 gm of soil +500 gm of water 2 gm of lime, ferric sulphate, ferric alum, sodium alum, or potassium alum, and filtering through the Pasteur-Chamberland filter, or centrifuging. The three last processes give a clear solution with a minimum loss of salt. Lime ferric sulphate and ferric alum cause a considerable loss of nitrates. In the determination of chlorides and nitrates nothing is to be gained by agitating the water and soil for more than 5 minutes, provided the soil is finely divided, and the solution vigorously shaken. A longer time of agitation is required in order to reach equilibrium in a soil solution in which sulphates are to be determined and the actual period will depend upon the quantity and quality of the sulphates present.

(1) See R Dec 1921, No 1199 (Ed)

When nitrates are to be determined in the soil solution and alum is used as the flocculent, no other antiseptic is necessary; where alum is not used and the solutions are to stand for some time, it is well to add 0.5 cc. of chloroform to each sample, more concordant results are however obtained when the analyses are made immediately and no antiseptic is used

377 - **Connection between the Hydrogen Ion Concentration of Soils and their Need of Lime.** — JOHNSON, H W (Iowa Agricultural Experiment Station), in *Soil Science*, Vol XIII, No 7, pp 7-22, figs 9, bibliography of 25 works. Baltimore, January 1922

In all the States situated in the wet zone of the United States, the phenomenon of soil acidity occurs, the nature of this acidity is not well understood and very various opinions are held as to its cause. It has been attributed to the presence of mineral or organic acids, to colloidal substances, to adsorption and absorption, and to the effects of specific compounds. More recently, however, the presence of hydrogen ions has been demonstrated and as they are an expression of acid reaction their occurrence denotes real acidity and not a property due to complex theoretical phenomena such as has hitherto been supposed. The presence of hydrogen ions having been proved, their concentration was determined by various authors. These ions may be derived from organic or mineral acids, acid salts, the salts of weak bases and strong acids, compounds which are found in all soils. In any case it is probable that the principal sources of the hydrogen ions of the soil are the acid silicates and the salts of weak bases iron and aluminum. The different views regarding soil acidity resulted in the adoption of different methods for its determination and the results obtained were so dissimilar that their value is doubtful. In some the apparent acidity was taken into account, in others the real acidity or the adsorption acidity, but in every case the results were expressed under the form of the soil's need of lime. As, however the comparative value of want of lime and of the hydrogen ions concentration has not been completely determined, the problem is to ascertain the connection, if any between the need of lime as determined by the various methods and the concentration of the hydrogen ions. If there is any definite connection, the need of lime can be expressed in terms of the hydrogen ions concentration, if no such connection exists, some explanation must be given for the inconsistency of the data relating to want of lime.

In order to decide this question, the author determined the need of lime and the hydrogen ions concentration in 50 very different soils, and found that there is no definite connection between need of lime, as determined by VEITCH's method (neutralisation by lime-water), and the concentration of the hydrogen ions determined by the hydrogen electrode. On the other hand, TRUOG's method (neutralisation by barium hydrate in the presence of carbon dioxide), gives results combining those obtained by VEITCH's method with the data given respecting the concentration of the hydrogen ions

In soils of similar type there is a connection between apparent acidity and real acidity.

The acidity of soils seems to be due to weathering and leaching, rather than to the accumulation of organic acids; the clay particles and the organic matter act as buffers to lessen the concentration of the hydrogen ions which proves that soil acidity is to be attributed to the disintegration and washing away of the mineral substances, and hence to the resultant formation of acid silicates.

To sum up, it is evident that in the generality of soils, the apparent acidity viz., the need of lime, is in no way connected with the real acidity represented by the concentration of the hydrogen ions; this is the case in soils of different types. On the other hand, where the soils are of similar texture, age, formation and organic matter content, there may be a correlation between the two factors.

G. A. B.

378 - **Stratification and Hydrogen-Ion Concentration of the Soil in Relation to Leaching and Plant Succession with Special Reference to Woodlands.** - SALTSBURY F. I., in *The Journal of Ecology*, Vol. IX, No. 2, pp. 220-240 figs. 10. Cambridge, February 24, 1922.

Natural woodlands exhibit a soil stratification in which a definite gradient can be recognised that is reflected in the macro- and micro-organic population. Owing to leaching action, the surface soil is poorest in bases which increase in amount with increasing depth. The organic content on the contrary diminishes with increasing depth associated with which there is a gradient of hydrogen-ion concentration attaining its maximum at the surface. Exceptions are encountered on highly basic soils where the manurial action of the dead foliage may result in a higher base content at the surface than just below the soil. In any case there is a fairly close relation between organic content and real acidity, and "buffer" action (or effect of the latent acidity) is shown to be greatest in the layer of maximum organic content. The view is advanced that woodlands in general and probably all types of undisturbed plant communities in England are tending to become progressively more acid with consequent changes in the character of the vegetation. High forest is most favourable to this succession, while the system of standards-with-coppice with short rotation period tends towards its retardation.

Woodlands occupying valley slopes are inclined to exhibit less marked surface leaching as one descends, and the chief differences between upland and lowland woods are regarded as related to this factor. A depression of vegetative zones related to soil factors is a natural outcome of this process.

G. A. B.

379 - **The Carbon Coefficient for Determining the Organic Matter in Soil.** - READ, J. W., and RIDGELL, R. H. (Arkansas Agricultural Experiment Station), in *Soil Science*, Vol. XIII, No. 1, pp. 1-6, bibliography of 9 works. Baltimore, January 1922.

The researches of SCHULZE, WOLFF, FRESSENIUS and van BEMMELLEN have contributed to extend the use of a conventional coefficient for estimating the organic matter content of soils from the amount of organic

carbon they contain. The value of this method has however been called in question on several occasions, and the author's work furnishes some conclusive evidence on the subject.

He determined the organic carbon present in 37 typical soils (superficial, and sub-superficial, subsoil), from various North American Experiment Stations; the determination of the organic carbon was effected at the same time as that of the organic matter and by means of a special rapid method of dry combustion.

The data obtained proved without exception that the coefficient 1.724 adopted in the belief that the humus contained 58 % of carbon, gives lower results than those obtained by direct determination. In fact, the carbon percentage of the organic matter present in the superficial layer of the soils examined varied from 30.20 to 56.27 %, with an average of 49.26 %, being less by 9 than the percentage obtained by means of the coefficient. In the case of the subsoil, the difference was even greater, the average amount of carbon in the organic matter being hardly 39.16. There is thus every reason to doubt the expediency of adopting an arbitrary coefficient for the carbon content of the organic substances found in the soil. In any case, more accurate results could be obtained by choosing a coefficient based upon a probable carbon content of 50-52 %.

380—**Studies on *Clostridium Pastorianum* as a Fixer of Nitrogen.**—I TRUFFAUT, G., and BEZSSONOFF, N., Augmentation du Nombre des *Clostridium Pastorianum* (Winogradski) dans les terres partiellement stérilisées par le sulfure de calcium, in *Comptes rendus de l'Académie des Sciences*, Vol CLXXII, No 21, pp 1319-1324. Paris, May 23, 1921.  
— II ID ID Sur les variations d'énergie du *Clostridium Pastorianum* comme fixateur d'azote, *Ibidem*, Vol CLXXIII, No 19, pp 865-870, November 7, 1921.

The effect of partial sterilisation, whether by heat or an agent with a calcium sulphide base, is proved by the fact that, out of 10 tubes of agar mixed with glucose and sown with control soil solution, only 3 fermented, although in the case of the same number of tubes containing partially sterilised soil, 8 underwent butyric fermentation even 8 days after treatment; after 16 days the ratio still remained as 1 to 2. Adopting the dilution method, the number of *Clostridium* per gram was about 100 000, but this figure is far below the real one. Even if it is accepted, it is from 10 to 100 times higher than the figures given by JONES and MURDOCH in the case of *Azotobacter*. The highest counts of these two authors give 1800 organisms per gram, whereas TRUFFAUT and BEZSSONOFF were only able to find 500. It would thus appear that (*Clostridium Pastorianum*, and not *Azotobacter*, is the principal agent of the fixation of nitrogen in the soil.

II. — The authors made 2 other experiments by partially sterilising a normal soil and making successive cultures from it. They consider themselves justified in drawing the following conclusions from the results obtained:

1) The partial sterilisation of the soil by means of calcium sulphide not only increases the number of the *Clostridium Pastorianum* in-

dividuals, but also their capacity for fixing nitrogen. This stimulating effect of partial sterilisation is lost after repeated culture in agar mixed with glucose.

2) There is in soil a factor that hinders the growth of *Clostridium* in artificial cultures made with it. The effect of this factor becomes imperceptible when these cultures are sown with dilutions of about 1/100 000.

G. A. B.

DRAINAGE  
AND  
IRRIGATION

381 - Irrigation Schemes in the Niger territory of the French Soudan. — See n° 417 of this Review.

382 - The Improvement of Arable Land and Meadows in Czecho-Slovakia. — *Bulletin of the Ministry of Agriculture of the Republic of Czecho-Slovakia*, Year III, No 1, pp. 1-2 Prague, January 1, 1922 (1)

Stock-breeding being the most important branch of Agriculture in the Czecho-Slovakian countries, meadow land is of equal importance with arable. According to statistics, there were in 1920 520 791 hectares of meadow land in Bohemia, 154 982 hectares in Moravia and 30 028 hectares in Silesia, the hay crop was 31 6 quintals per hectare in Bohemia, 29.4 quintals in Moravia and 18 3 quintals in Silesia. The average hay crop is much less than in Germany as the land has not as yet been sufficiently improved. The largest yield per hectare is in the Czecho-Moravian mountains, next come the crops of the Forest of Bohemia (Sumava), and of the Sudetes. The total hay production of Bohemia in 1909 was 16 500 000 quintals, with a value of 136 millions of crowns.

The land improvement works are subsidised by the State and the Local Administrations, the latter having opened Land Improvement Colleges with the object of training the necessary staff. There are 2 such colleges in Bohemia the course lasting for 2 years. One of the Colleges is at Vysoké Myto and the other at Cheb. In Moravia, there is a third College at Roznov. These Colleges are provided with all the means of instruction, collections and laboratories, a botanic garden, experiment fields and a large experiment farm. The students are chiefly instructed in the science of improving fields and meadows, that is to say, drainage work, constructing irrigation and hydraulic works, aqueducts, road-making and land division etc. After completing their course the students are found posts on the staff of the Provincial Agricultural Councils, in Cooperative Societies for land-improvement, or are employed by Agricultural-engineers in charge of hydraulic works, in some cases they are authorised to carry out less important work on their own responsibility.

The Ministry of Agriculture makes a grant for the improvement of pastures. The neglected grazing-grounds of the Bohemian Forest have been taken in hand with the result that the returns have been increased by 3 million crowns.

The principal means by which the forage crops are increased is by carrying out drainage or irrigation works, or both simultaneously.

(1) See R Dec. 1921, No 1191 (Ed)

Since 1908, an increased development of hydraulic works can be observed. As the duties of the Bureau of Hydraulic Operations, attached to the Council of Agriculture in Prague were continually increasing, branch offices have been opened at Chlumec n. C., Králové, Hradec, Kutná Hora, Hostelec n. O., Velvary and at Soběslav (for the improvement of peat-moors). The impetus that has been given to improvement works in Bohemia is shown by the Statistics for the improvement of arable land and meadows, which give the total superficial area improved between 1885 and 1907 as 35 384 hectares, and the expense of the respective operations as 35 293 000 crowns.

Owing to the improvement of the meadows, the yield per hectare has risen to 50 quintals of hay, and when all the meadows of Bohemia have been improved, the value of the total hay crop will rise from 136 438 crowns (1905), to 71 700 000 crowns. The area of meadow land that has deteriorated from excessive moisture is reckoned at 500 000 hectares, not counting the peat-moors which cover 20 000 hectares.

In Bohemia, as in all the other Provinces, the improvement operations have passed by successive stages from open ditches to pipes buried in the ground. The drainage system is known by different names, according to the materials employed for the work, stones, wood, rods, bricks and pipes.

The improvement work is carried out under the supervision of the Improvement Cooperative Societies which are established in accordance with a law giving them a right to the grants made for the purpose by the State and Provincial Administrative Authorities. These Cooperatives are united in a Confederation at Prague.

Peat-moors are very common in the mountains: the Bohemian Forest, Sudetes, Czecho-Moravian mountains, the neighbourhood of Třeboň, and Blatná and in the basins of the rivers Labe and Jizera.

The improvement of the peat-moors would result in a profit of 6 million crowns. In Bohemia, they are cultivated according to the methods employed in Germany, the Netherlands etc. There are also several factories in Bohemia (Stráž, Nové Hradky and Bastianberg), where excellent peat-moss litter is made.

In the 1922 Budget of the Ministry of Agriculture of the Czecho-Slovakian Republic, the sums allocated to land improvement amount to 23 900 000 crowns; in the Budget of Bohemia, 4 480 000 crowns were set apart for this purpose as against 5 230 000 crowns in Moravia and 64 672 crowns in Silesia.

383 - **Further Experiments with Activated Sludge in England.** — RICHARDS, E. H. and SAWYER G. C. (Rothamsted Experimental Station), in *Journal of the Society of Chemical Industry*, Vol. XLI, No. 5, pp. 62-70. London, March 15, 1922.

MANURES  
AND  
MANURING

Preliminary experiments carried out at Rothamsted on the fertilising value of slate-bed and activated-sewage sludge have recently been described (1). The present communication deals more particularly with

(1) See R. 1920, No. 843. (Ed.)

attempts to answer the following questions : 1) Does the activated sludge method recover more of the nitrogen in sewage than the older methods of sewage purification ? 2) Is the nitrogen recovered in the sludge in a form available as plant food ? 3) What is the source of the high nitrogen content of activated sludge ? The enquiry was undertaken at the request of the Ministry of Agriculture, most of the expenses being met by a grant from the funds of the Ministry. In order to test the fertilising value of activated sludge on the field scale and at the same time to obtain information on these points, it was desirable to have a small plant working under direct control and concurrently with the laboratory experiments.

The results of these experiments may be summarised as follows.

1) If activated sludge is aerated for a short period in an ammoniacal solution, the recovery of the nitrogen is quantitative. The nitrogen not found as ammonia or nitrate in the effluent is recovered in the sludge.

2) If aeration is continued, loss of nitrogen occurs and this loss is roughly inversely proportionate to the volume of sewage present.

3) The same effects are observed with sewage. The ammonia falls, while the sludge gains nitrogen with a loss of nitrogen on the whole balance after 16 days' operations.

4) There is considerable evidence to shew that the extra nitrogen in activated sludge, over and above that found in the old type sludges, is derived from the ammonia of sewage. There is no evidence of fixation of atmospheric nitrogen.

5) The number of protozoa in well-activated sludge approximate to 1 000 000 per gram of wet sludge. The cell content of these organisms alone may account for a large proportion of the extra nitrogen.

6) There is complete correlation between the numbers of active protozoa and bacteria in activated sludge under varied conditions of working.

7) The increase in bacterial numbers following suppression of the protozoa produces no improvement in purification of sewage. There is, however, a change in the bacterial flora, nitrifying organisms being suppressed by the partial sterilisation. When nitrifying organisms were reintroduced, a greater quantity of nitrate was found in the partially sterilised than in the untreated sewage. The experiments did not, however, enable the investigators to decide whether this is due to larger production or a decreased destruction of nitrate.

Simultaneous experiments carried out at the experimental sewage plant, in which a domestic sewage of rather above average strength and a small proportion of detritus were used, resulted in the production of activated sludge containing 3.5 to 6.8 % of nitrogen calculated on the dried sludge. Very great variations in the methods of working (e.g. in the volume of air, strength of sewage, amount of sludge in tank, and time of retention), produce no appreciable change in the nitrogen content of the sludge. Observations made in working the experiment tank confirm the laboratory experiments designed to find the source of the extra nitrogen content of activated sludge compared with ordinary sewage sludges. They

afford no evidence of fixation of atmospheric nitrogen, but suggest that, in addition to colloidal nitrogen, ammonia is removed from the sewage by physical or biological means or both. Under strongly aerobic conditions, and with a less proportion of sludge in the tank (less than 25 %), the recovery of sludge is practically quantitative (colloids neglected), i. e., its weight is practically the same as the weight of suspended solids in the sewage. If aeration is moderate to poor, and if the volume of sludge is allowed to accumulate up to 50 % or more, over half the dry matter in the suspended solids of the sewage disappears. Variations of conditions influence the nitrogen changes in a similar way, but there is always a loss of nitrogen — under favourable conditions 20 %, under unfavourable 80 % of the nitrogen left in the tank is not recovered.

The proportion of total nitrogen recovered from sewage in normal working by the activated sludge method is greater than by the older methods of sewage purification, viz 15 % compared with 10 % obtained by precipitation and 4 % by septic tanks. With sewage of half the average strength and supplying twice the normal volume of air per gallon of sewage, the recovery of nitrogen was 27 % of the total nitrogen in the sewage.

The tank experiments also brought out 2 other important points  
a) the great increase in availability of the nitrogen by activation, under continuously aerobic conditions 66 % of the total nitrogen is nitrified in 100 days (under less aerobic conditions only 40 % of the nitrogen in the activated sludge is nitrified), compared with 15 % of sewage solids, and if the latter had been lagoon-dried, probably not more than 5 % of the nitrogen would have been available.

The phosphoric acid content of samples of activated sludge is much higher than that found in the old type sewage sludges examined by the Royal Commission (1). These contained from 0.66 to 1.11 % phosphoric acid compared with 2.8 to 3.8 % in activated sludge. The same applies, but in a less degree, to the potash. The amounts of phosphoric acid and of potash have not much manurial importance, but their relation to the high nitrogen content of activated sludge is suggestive of a common biological origin.

Field trials were made with activated sludge at Rothamsted Farm, the first lot was applied to plots for grass and barley, the second for potatoes. No attempt was made to dry the sludges beyond about 90 % moisture content, and they were applied in a pasty condition which made uniform distribution rather difficult. The results obtained showed that generally speaking, activated sludge gave good yields in comparison with sulphate of ammonia and farmyard manure, the nitrogen ratios being equal. It must be remembered that rather less than half the nitrogen in the activated sludge is available in 100 days, while practically the whole of that in the sulphate of ammonia can be nitrified in the time. There is one important difference between the results of these field trials and those ob-

(1) See R 1015, No. 795. (Ed.)

tained in the preliminary pot-culture experiments, described in the beginning of the article. The dried sludge gave very uniform results in pots, but the wet sludge gave much greater differences between the yields of individual plots than is usual in this class of work. This effect was noticeable with all 3 crops, but no satisfactory explanation can be given to account for the bad agreements between duplicate plots. In any case, however, these field trials show that activated sludge has a high manurial value in marked contrast with the old type sewage sludges tested on the Rothamsted farm in past years

384 - Experiments with "Rhenania Phosphat" in Germany. — REMY, Th and WEISKE, F (Aus dem Institut für Bodenlehre und Pflanzenbau an der Landwirtschaft Hochschule in Bonn-Poppelsdorf), in *Landwirtschaftliche Jahrbücher*, Vol LVI, No 1 pp 1-57 Berlin, 1921

The authors have continued their manurial experiments with "Rhenania phosphat" (1) which is obtained by calcining a mixture of phonolite and crude, poor phosphates rich in lime. Six years have elapsed since the first researches were made without any attempt at experiments on a sufficiently large scale. The experiments made in Belgium with a similar product known as "Vesta" phosphate (2) gave excellent results on the whole as compared with those obtained by the use of either superphosphate or basic slag. In the opinion of GRÉGOIRE, "Vesta" phosphate has also an energetic fertilising action, and it would appear that its phosphoric acid and potassium are quite as readily assimilated as that of basic slag and the potassium of the potassic salts used as fertilisers respectively.

The authors undertook 2 series of experiments, one to test the action of "Rhenania phosphat" in the capacity of a phosphatic fertiliser, and the other to determine its action as a potassic fertiliser. They adopted the following methods:

1) Except in special cases, they always compared equal quantities of the total phosphoric acid.

2) They always compared the potash of "Rhenaniaphosphat" with a parallel series of leucitic potash obtained by the fusion of lime with leucotephrite.

3) Since "Rhenania phosphat" and basic slag both contain basic lime, the authors took into account the amount of the lime in the above-mentioned products.

4) The potassic fertiliser was always spread before sowing and mixed with the upper 30 cm of soil.

5) The basic fertiliser on the contrary was applied in successive doses.

The experiments were carried out in pots with an artificial soil made by mixing clay with quartz sand, peat, calcium carbonate and ground phonolite. The plants chiefly grown were *Cruciferae* (as being very susceptible to phosphatic fertilisers), hairy vetch, tobacco and potatoes.

(1) See R 1916, No 496 (Fd)

(2) See R 1919, No 572 (Ed)

The following conclusions may be drawn from the results obtained :

a) Approximate equivalence of the phosphoric acid soluble in citric acid present in " Rhenaniaphosphat " and basic slag in 6 out of 10 experiments.

b) The action of the total phosphoric acid of basic slag and of " Rhenaniaphosphat " was equal in 3 out of the 13 cases mentioned.

c) In 4 cases the action of total phosphoric acid of " Rhenaniaphosphat " was greater than that of the phosphoric acid in basic slag.

In 40 % of the cases, the action of the phosphoric acid of " Rhenaniaphosphat " corresponded to its solubility in citric acid ; on the other hand, it was greater in 60 % of the cases. This difference in the results depends partly upon the intimate composition of the fertilisers compared and partly on external circumstances.

In the experiments relating to potassium, it was found that it was used in the proportion of 47 to 100 % (average 73 %), of the corresponding value in potassium of potassium chloride. It may safely be said, that the potassium of " Rhenania-phosphat " corresponds to 81 % of an equal amount of potassium in the form of potassium chloride and sulphate. Owing however to the method of manufacture the availability of the potassium decreases as the action of the phosphoric acid increases, but this has only a secondary effect on the total results, because a " Rhenania-phosphat " containing 12 % total phosphoric acid and 3 % potassium would be worth per quintal 60 marks for the phosphoric acid and 1.50 to 2 marks for the potassium, so that the latter becomes a gratuitous supplement to the phosphoric acid.

As regards solubility in citric acid, the phosphoric acid of " Rhenaniaphosphat " would seem inferior to that of basic slag. There is, however, no strict proportionality between this solubility and the fertilising power of phosphoric acid, and no results could be obtained from researches in this direction.

385 - **Results of Two Years Experiments with Superphosphate " Tetraphosphate " and Phosphorite in Italy.** -- AVANZI E. (Istituto Agrario della R. Università di Pisa, in *L'Agricoltura Italiana*, Year XLIV, Parts 1-5, pp. 145-155, Bibliography, Pisa, 1921 (1).

These experiments were undertaken with the object of making some contribution to the much discussed question of the efficacy of " tetraphosphate " as compared with mineral superphosphate and phosphorite. They were carried out in two adjoining fields divided into 8 plots. Maize was grown in the fields in 1918, and winter wheat in 1918-1919 ; the maize succeeded a temporary winter pasture fertilised with farmyard manure ; the wheat had been manured with nitrate of soda. The total phosphoric acid content of the superphosphate used was 15.10 %, of which 14.65 % was soluble in water and citrate of ammonium. The tetraphosphate was found by analysis to contain 26.22 % phosphoric acid of which 1.68 % was soluble in 1 % citric acid, while the phosphorite contained respective-

(1) See R. 1920, No. 498. (Ed.)

ly 26.70 and 2.12 % ; both the latter compounds were equally finely ground. The phosphatic fertilisers were applied to the maize at the rate of 4 quintals per hectare in the case of all except the control plots.

In the following table the author gives a summary of the results obtained. He calculates the yield indices from the average weight of the crops obtained from the control plots and brought up to 100.

Fertilisers	Maize (1st year)		Wheat (2nd year)	
	Grain	By-products	Grain	By-products (straw and grass)
None (control). . . . .	100	100	100	100
Phosphorite . . . . .	100	101	101	100
Tetraphosphate . . . . .	109	108	105	105
Mineral superphosphate . . . . .	120	112	112	106

In order to be able to estimate these results accurately, it must be understood that the productive capacity of the land was high, owing to manuring and working in the preceding years. Hence none of the differences are observed which would occur in the case of soils that had never been fertilised. The differences between the effects of the fertilisers applied are however so noticeable that the following conclusions can be justified.

- 1) The phosphorite had no appreciable effect upon either the first or the second crop.
- 2) The tetraphosphate exerted a beneficial effect upon both the first and the second crop.
- 3) The action of the tetraphosphate upon both crops was less than that of the mineral superphosphate, although the latter had a considerably lower phosphoric acid content. Further, as the difference in the price of the phosphoric acid unit was not proportional to the difference in the efficacy of the two fertilisers, the inferiority of the tetraphosphate is absolute.

Two points still remain to be decided : *a*) whether under other conditions tetraphosphate would behave differently as compared with superphosphate and phosphorite ; *b*) the efficacy of tetraphosphate as compared with basic slag. When these points are settled, it will be necessary to consider the economic aspect of the question.

In any case in order to arrive at some definite conclusion respecting the desirability of using phosphorites, and the superiority of one phosphatic fertiliser over another, it would be advisable to carry out further experiments with the object of comparing one or more ground phosphorites with superphosphates, and more particularly with the tetraphosphates obtained from each phosphorite.

386 - **Studies on Sulphur as a Factor in Soil Fertility.** — I WOODWARD, J (Contributions from the Hull Botanical Laboratory 289), in *The Botanical Gazette*, Vol LXXIII, No 2, pp 81-100, bibliography of 73 works. Chicago Ill., February 1922 — II BUSANELLI, L. S. (Chief Chemist, Iseopet Sulphur Company), A Historical Review of the Research showing the Fertiliser Value of Sulphur in *The American Fertiliser*, Vol LVI No 4, pp 80-86 Philadelphia February 25, 1922.

I — This investigation was conducted under the terms of a research fellowship from the Gypsum Industries Association in the United States. Basing his opinion on the analyses made by ROBINSON (1) which show a wide variation in the sulphur content of different soil types the author considers that other types of soil should be analysed to discover their sulphur as well as their phosphorus content and that it is also necessary to conduct field experiments. He therefore analysed 34 average soil and sub soil samples from Indiana Kentucky Michigan Ohio and Wisconsin for phosphorus sulphur and the loss on ignition. Fertilising experiments with gypsum were made at the same time in the field of Indiana and Kentucky whence the samples had been taken.

The analytic data show a general relation between the sulphur content and the loss on ignition in soil samples of the same or closely related soil types but this relation is not apparent when different soil types are compared. The sulphur contents in the surface soil vary from 0.0118 to 0.0905 per cent while the phosphorus contents vary from 0.0360 to 0.3407 per cent. All the upland and most of the alluvial soils are poor in sulphur the high phosphorus content of most of the Kentucky soils and one of the Indiana soils is undoubtedly due to the influence of the rock from which they were derived this being the case with the Kentucky samples a limestone rich in phosphorus. If the sulphur and phosphorus content of the surface soil (the upper 15 cm.) are calculated and compared with the amounts removed by maximum crops of maize wheat timothy clover and lucerne it is found that the highest sulphur content is sufficient for only 39 years of lucerne 139 of clover 159 of timothy 355 of wheat or 232 of maize whereas the lowest sulphur content is sufficient for only 5 years of lucerne 18 of clover 21 of timothy 46 of wheat or 30 of maize. The lowest phosphorus content is equal to the amount removed by 42 years of maize 60 of wheat 80 of timothy 36 of clover or 20 of lucerne. On the other hand the maximum phosphorus content would be enough for 401 years of maize 568 of wheat 757 of timothy 341 of clover or 189 of lucerne.

On some of the soils tobacco clover and lucerne were benefited by the use of gypsum. The results are however not quantitative. More field experiments are needed and greater care should be taken to eliminate other factors interfering with the effect of the gypsum. Each treatment should be repeated in order to reduce the probable error. More satisfactory results would probably be obtained if the work were confined to one field for each soil type and if each treatment were applied to from 3 to 5 plots in the same field.

(1) See *R. I. R.*, No 11 (1922).

II. — The author reviews the literature (especially the American literature), dealing with the question of the fertilising value of sulphur and reminds the reader that much less is known about the transformations of sulphur in the soil than about those of nitrogen. The reason is that sulphur is very rarely deficient in soils, and the subject has never been considered of sufficient practical importance to justify extensive investigations.

Instead of thinking of the nitrogen-phosphorus-potash formula as representing a complete fertiliser, it is time to work solely from the standpoint of limiting factors including not only the three above-mentioned, but also sulphur, lime, magnesium and any other factors that influence crop production.

The early failures with gypsum were probably due to the fact that phosphorus or some other element besides sulphur was limiting growth, or that sulphur was not the element required. In any case, the facts recently brought out in regard to sulphur should lead at once to a widespread re-examination of these problems with more carefully designed and more rigidly controlled experiments.

390 — **Occurrence of Quercetin in a Type of Brown-Husked Maize.** — SANDO, C. E. (Junior Chemist, Office of Physiological and Fermentation Investigations, Bureau of Plant Industry, U. S. Depart. of Agric.) and BARTLETT, H. H. (Department of Botany, University of Michigan, Collaborator, Office of Physiological and Fermentation Investigations, Bureau of Plant Industries, U. S. Depart. of Agric.), in *Journal of Agricultural Research*, Vol. XXIII, No. 1 pp. 1-4. Washington, 1921.

In connection with the genetical studies of pigmentation in maize, which have been carried on for several years at Cornell University, the authors made parallel biochemical studies in the isolation and identification of the pigments from material of known genetical constitution. The brown-husked type of maize contains a flavonol viz., free quercetin, and a quercetin glucosid.

The two compounds are both lemon-yellow in colour. If they account for the truly brown colour of the husks of this type, it must be through their tinctorial quality, probably through their adsorption on some colloid component of the brown tissues. It is very probable that the quercetin glucosid is the counterpart in the brown type of the anthocyanin of the purple type of which the pigment will probably be found to be allied to cyanin.

391 - **Composition of Wild Beets.** — SAILLARD, E., in *Comptes rendus de l'Académie des Sciences*, Vol. CLXXIV, No. 6, pp. 411-412. Paris, February 6, 1922.

The author gives the results of the analysis of two lots of beetroots coming from Primel-Trégastel (Finisterre), and forwarded to him at the request of SCHRIBAUX. The data obtained may prove useful to the breeder who is seeking for roots specially adapted to industrial requirements and capable of transmitting their characters.

*Consignment of October 26.*

	Average	Maximum	Minimum
Weight of roots . . . . .	17 gm.	56 gm.	10.80 gm.
Dry matter . . . . .	32.18 %	35.22 %	29.64 %
Sugar . . . . .	15.95	19.60	13.80
Ash . . . . .	1.73	1.98	1.32
Insoluble pulp . . . . .	9.12	10.48	7.24
Carbonised ash in the residuum . . . . .	0.46	0.56	0.20
Nitrogen . . . . .	0.84	0.98	0.63
Water + sugar . . . . .	83.50	84.38	82.88

These beets, which are smaller and more woody than the beets used in sugar manufacture, also contain more dry matter, as well as more insoluble pulp, more total nitrogen, more mineral substances (about 2 ½ times as much), and more chlorine, sodium, magnesium, and phosphoric acid.

Their sugar content is equal to or higher than the sugar content of the industrial beets; their sap is less pure and the sum water + sugar lower.

*Consignment of December 14.*

Sugar . . . . .	13.00 to 15.56 %
Dry matter . . . . .	26.40 to 28.40
Carbonised ash . . . . .	0.98 to 1.28
Total nitrogen . . . . .	0.33 to 0.49
Insoluble pulp . . . . .	9.00 to 9.90
Carbonised ash per 100 of residuum . . . . .	0.34 to 0.40

The figures obtained from this consignment were thus lower than in the case of the first.

These results show that wild beets can be found with as high a sugar content as cultivated beets grown for industrial purposes P. C.

392 - **Formation of Alkaloids in Belladonna Leaves, in Relation to Solar Radiation.**

— See No. 429 of this Review.

- 393 - **The Influence of Light and of Fluctuating Temperatures on the Germination of *Poa compressa*.** — FRYER, J. R. (Department of Field Husbandry, University of Alberta), in *Scientific Agriculture*, Vol. II, No. 7, pp. 225-230, figs. 5. Gardenvale, P. Q., March 1922.

It has been observed that the satisfactory germination of *Poa compressa* L. is more or less uncertain. In samples, which on external examination, appeared to be full of life, sometimes only 10 to 20 % of the seeds germinated, whereas for other samples of similar appearance the germination percentage rose to 50 or 60 %. Moreover the same samples, when retested, frequently gave results differing widely from those obtained the first time. General observations led to the belief that sunlight and fluctuating temperatures were beneficial to the germination of this seed, but no definite data had been obtained and no literature dealing with the subject was available.

The author made an experiment on the influence of sunlight upon the germination of Canada Blue Grass (*Poa Compressa* L.), and took 12 seed samples for the purpose. Simultaneously with the above tests another experiment was conducted for the purpose of studying the effect of steady temperatures and of fluctuating temperatures. The results showed that sunlight has a somewhat beneficial effect upon the germination of *Poa compressa*. Daily fluctuations of temperature ranging between 15° C and 35° C are probably the best temperature conditions for germination.

G. A. B.

- 394 - **Effect of Soil Temperature upon the Development of Nodules on the Roots of certain Leguminosae.** — JONES, F. R. (Pathologist, Office of Cotton, Truck and Forage Disease Investigations, Bureau of Plant Industry, U. S. Dept. of Agric.) and TISDALE, W. B. (Instructor in Plant Pathology, University of Wisconsin), in *Journal of Agricultural Research* Vol XXII No 1, pp 17-31, figs. 4, pl 3. Washington, 1921

The study of a diseased crop of lucerne suggested the idea that soil temperature might affect the development of nodules on the roots of lucerne and perhaps all other leguminosae to such a degree that the assimilation of nitrogen by these plants is greatly modified during the summer. The researches described in this article were carried out with the object of investigating the question. Preliminary studies were made upon the effect of soil temperature on the development of 4 leguminosae; lucerne, red clover, field-peas and soy-beans with special reference to its effect on the infection of these plants by *Bacillus radicicola* Beijer., and the subsequent development of nodules. The greater number of the data were obtained by growing plants in soil kept at a series of temperatures, ranging from 12° to 36° C with variations of 3° between each. The air temperature was uniform for all the plants, ranging from 14° to 20° C.

As was anticipated, the 4 plants differed in their ability to tolerate soil temperatures at the extremes of the series. Thus peas were dwarfed at 30° C; clover developed poorly at 36° C while lucerne and soy-beans grew very well at that temperature. Soy-bean plants grown in soils kept at 12° — 15° — 33° — 36° C had very dark-green leaves, whereas the foliage

of those towards the centre of the series became progressively lighter, the lightest leaves being found at 24° C

With regard to the number of nodules formed on plants grown in soil kept at these series of temperatures, irregularities were found in each series, but no large and consistent differences were discovered, except that at the extreme upper and lower temperature limits tolerated by the plant the number of nodules was reduced, although peas usually produced a greatly increased number of nodules at 30° C. In short all the species studied form nodules in soils at any temperature at which the plant can make a growth that is at all vigorous

While the variation in the number of nodules was not consistent their size measured by the average dry weight per plant was found to differ greatly and consistently within the series at least so far as the soy-bean was concerned. The maximum weight attained for a soy-bean plant after a period of two months was found at a soil temperature of 24° C. Examination of nodules on the roots of the other Leguminosae indicated that their maximum production occurred at about the same temperature

The weight of the nodules produced by soy-beans was not found to be correlated with the weight of tops or roots through the series of temperatures. In fact the weight of the tops was practically as great at 30° to 36° C as at 24° C while the weight of the roots declined rapidly at the higher temperatures. The weight of the roots likewise showed no such diminution at the higher or lower temperature as did the weight of nodules. With the soy-bean plant and to a much less marked degree with the other plants there was a correlation between weight of nodules and colour of plants, the largest weight of nodules occurring on plants with the palest green colour. Generally speaking, plants with large nodules had a higher percentage of total nitrogen in the tops though this correlation is not exact

As regards the factors of soil environment that may exert an influence upon nodule formation such as moisture, concentration of nitrates and hydrogen-ion concentration of the soil solution it does not appear that their variations, influenced in any way the differences in nodule development recorded at the different temperatures in these series. G A B

395 - Observations on Heredity made at the Phytotechnical Station at Abed (Denmark). VIELERGAARD H A B in *Zeitschrift für Pflanzenzuchtun* Vol VIII Part pp 19-115 Berlin, September 1921

PLANT  
BREEDING

A series of experiments on lupin, wheat and barley have recently been carried out at the Phytotechnical Station of Abed (Denmark). The following are some of the results obtained

1) LUPIN - *Lupinus angustifolius* is a blue-flowered variety but contains individuals having both red and white flowers

From the cross *white* × *blue* were obtained in the  $F_1$  exclusively blue-flowered individuals, and in the  $F_1$  blue and white offspring in the ratio of 3 : 1 — From the cross *red* × *blue*, blue-flowered hybrids were obtained in the  $F_1$ , and in the  $F_2$  blue and red-flowered plants in the ratio of 3 : 1

The *blue* × *red* cross gave in  $F_1$ , blue individuals and in the  $F_2$ , blue, red and white flowered plants in the ration of : 9 : 3 : 4.

There would appear to be two genetic factors concerned, B and R, in the case of the blue flowers ; B by itself gives rise to white flowers, and R to red flowers.

2) BARLEY. — In 1916, there appeared in a line of native barley, No. 867, eight abnormal plants characterised not only by their stiff straw but also by having only 6-7 very closely growing grains situated at the tip of the ear. These seeds were sown ; 36 abnormal and 4 normal plants being obtained ; the abnormal produced in their turn (in 1918) abnormal progeny only, whereas the offspring of the normal plants consisted of normal and abnormal individuals in the ratio of : 3.35 : 1.

The anomaly was probably the result of mutation in a 1914 plant, but owing to the dominance of the normal type, it only came to the light in 1916 as a consequence of segregation.

3) WHEAT. — As a result probably of mutation, a speltoid type of wheat was discovered in a line of wheat known under the name of Abed Storalks (large-eared Abed), and derived from Square-head. The new type differed from the original line in having longer, weaker culms, and longer, thinner and less dense ears. The progeny of the mutant was composed of speltoid and of normal types in the proportion 1 : 1. The normal plants produced exclusively normal descendants, whereas the speltoid continued to segregate into normal and speltoid individuals in the proportion 1 : 1, and may give rise to new types. In this way amongst others a dwarf form and an awned speltoid form have been obtained.

397 - **Experiments in Selection and Hybridisation made with the object of obtaining Types of Oats for Norrland (North Sweden).** — NILSSON-EHLE, H., in *Sveriges Utsädesförening s Tidsskrift*, Year XXXI, Part 5, pp. 200-215. Malmö, 1921.

In Sweden owing to high latitude and varying altitudes, there are great differences in the climates of the physiographical zones ; it is therefore necessary, in the case of every species of agricultural plant, to obtain distinct types specially adapted to each zone. This fact was recognised from the beginning of plant-breeding and selection in the country. Early maturing kinds of oats must be chosen for Norrland in order that the crop may ripen before the first autumn frosts. The species of oats indigenous to this region have succeeded in the course of time in adapting themselves

to their northern environment with its short summers and small sum total of heat. They ripened much earlier in the comparative cultural experiments than the varieties from districts lying further south. These native oats of North Sweden, although differing greatly from one another in many of their characters, share the following defects: low yield; poor quality of grain (the caryopsids are small and the glumes form a high percentage) weak straw.

There are 3 varieties:

1) *Nordsvenska hvithafren* (White Oats of North Sweden), very early, grown in South and Central Norrland;

2) *Nordfinsk svarthafren* (Black Oats of North Finland), very early, grown in Upper Norrland.

3) *Meröhafren* (Meroe Oats), native Norwegian oats of Meroe in the Nordlanden

Two other very early varieties, *Mesdag* and *Tyskmosshafre* have recently been widely grown in Northern Sweden

The cultural experiments made at Svalöf have demonstrated the yielding capacity of the early types. Guldregn produces a crop from 30 to 40 % higher on an average than Mesdag and Nordfinsk. There is therefore nothing surprising in the attempts made by agriculturists to introduce into the northern provinces good, heavy yielding, and relatively early-maturing varieties, such as Ligowo and Guldregn. Good results may be obtained from these varieties in hot years and favoured districts, but in ordinary cold seasons, the setting and ripening of the grain is hindered by the low temperatures, so that the yield of these oats in spite of their specific productivity is lower than that of Mesdag.

Hence it is necessary to obtain for North Sweden a type of oat combining the characters of early maturing and specific productivity in order that the grain may develop and ripen in good time. The combination of these two characters has been the object of much research and of many experiments along the lines of physiological selection and hybridisation

**SELECTION.** — By means of pure line selection, positive results have been obtained with the Meroe oats from which have been derived a new type 0668, which is both early maturing and productive.

Since however the quality of the grain is poor (the seed being small and having a high percentage of glumes), this new product cannot be used directly, but forms excellent material as a base for further crossing experiments.

"Nordsvenska hvithafren" is also not at all homogeneous, but since it is made up of many distinct forms, it could be improved by sorting

From 1900-1906 the author carried out a continuous series of selections, taking as his starting point the large amount of material collected in 1899 by Prof. HJALMAR NILSSON in the province of Dalarna. The final product of this selection was type 0924 (*Svalöf förädlade Dalahafre* = Dala oats selected at Svalöf), which is markedly superior to the population from which it was derived as regards the quality of the grain.

**CROSSING.** — The crossing experiments were begun in 1903. Their

chief object was to combine in a single type the good grain quality and high yield of the best varieties with the early-ripening of the oats indigenous in the North. The experiments began with the series Ligowo  $\times$  0660 (0660 = pure line of *Nordfinsk Svarthaire*) and Ligowo  $\times$  0668 (Meroe pure line). Ligowo is distinguished by the good quality of its grain. In the  $F_2$  (1905), as might be expected, very complicated segregation took place.

Out of 670 individuals of Ligowo  $\times$  0665 a certain, but not very high number have the early-maturing character of the 0668 parent. The seeds of 43 of the plants, that were earliest both in heading and ripening, were sown in the same number of plots. From the best of these plots, a new individual selection of 57 plants was made and their seed sown in 57 plots. Some of the most typical and uniform individuals were harvested together and the seed used *en masse* for the raising of a new strain which gave most promising results during the comparative experiments of 1908-1911. After this date, 32 new lines were selected, one of them being put on the market in 1920 under the name of *Orion* Oats b; this represented the final results of the cross Ligowo  $\times$  06608.

From Ligowo  $\times$  0660 was subsequently obtained by similar methods the *Byrn* Oat which proved superior to *Orion* in the Southern part of Norrland. Lately however it has been surpassed by *Odal* which tends to replace it.

Finally in 1906, the cross Guldregn  $\times$  0924 (selected Dala) was made. Guldregn is distinguished by its high yield, the good quality of its grain and the vigour of its culms. From this cross was obtained by final selection the line 01163, which combines in satisfactory proportions the characters of both parents and was put on the market in 1921 under the name of *Odal* Oats.

From what has already been said, it may be concluded that the pedigree selection of native oats and the crosses made have given positive results in the right direction.

In fact from the cross Ligowo  $\times$  0668 was obtained *Orion*, a type particularly suited to the interior and north of Norrland and to the highest zones. It combines with early ripening good quality and quantity of grain and straw; and its culms are more vigorous than those of 0668.

*Odal* would appear to be the type most adapted to the southern portion of Norrland.

There is no doubt that in these two cases early maturity and productivity have been successfully combined in good proportions with other valuable characters, and it is certain that further improvements can be obtained by continuing to work with uniformity of method along the present lines.

398 - **Researches on the Question of a Fatuoid Mutation of *Avena Sativa*.** - ÅKERMAN, A., in *Series Utsädesföremåns Tidskrift*, Year XXXI, Part 6, pp. 266-268. Malmö, 1921.

In the sowings of cultivated oats (*Avena sativa*) individuals are sometimes found that differ in many points from the common type and bear a

certain resemblance to *Avena fatua*. Thus the glumes (including those of the 2nd and 3rd grain), are furnished with a strong curved awn, while at the base, at the height where the ripe grain becomes detached, the calus is surrounded by a projecting ring of tissue. There is also a tuft of stiff hairs at the base of the seeds.

These aberrant forms, known under the name of *Fatuoiderna* (= Fatuoid), appear not only in the pure lines, but also in the mixed populations.

In addition to these fatuoid forms, other forms evidently of hybrid origin (heterozygotes) are occasionally seen which naturally have a greater resemblance to the normal type.

The progeny of these heterozygotes segregate into *normal*, *heterozygous* and *fatuoid* forms in the ratio 1 : 2 : 1.

The question of the origin of these forms arises. It was at first assumed that they were due to a natural cross between cultivated and wild oats, but this appears not to be the case, for in the first place, *Avena fatua* is not found in the district of Svalöf where NILSSON-EHLE has made a prolonged study of these anomalous forms, and in the second, as has been shown by the results of TSCHERMAK and SURFACE's hybridisation experiments the segregation in the case of true crosses is very complicated, a large number of characters being involved.

In the present case, except for the few points of difference mentioned above, the new and the original form are precisely similar.

If a hybrid origin is excluded, the fatuoid form must be regarded as a true mutant.

399 - **Rice Selection in the Philippines.** - See No. 409 of this Review.

400 - **Behaviour of the Hybrids *Medicago sativa* × *M. falcata* from the Standpoint of the Production of Types of Lucerne Suitable for Central Sweden.** - WITTE, H., in *Sveriges Utsädesförenings Tidskrift*, Year XXXI, Part 5, pp. 185-168 Malmö, 1921.

The author first gives a short account of the cultural experiments carried out in different countries with the object of discovering the most valuable types of lucerne. In Sweden, where lucerne is only grown in the Central and Southern provinces, the best results were obtained with Hungarian lucerne and *Medicago variegata* (*M. sativa* × *M. falcata*), and the latter could with advantage be substituted for the Hungarian variety in districts where great vigour and high resistance to cold are specially required.

The author has for some years been making a number of experiments and researches at Svalöf. From the results obtained, he is led to the conclusion that the climatic conditions of Sweden (heavy rainfall and low temperatures), are not favourable to common lucerne from the point of view of seed production. The plant flowers freely but a very small percentage of the blossoms only set seed.

In 1912, the following seed crop was obtained by the author from 13 strong, well-developed plants :

From 1 plant . . . . .	no seeds			
" 8 plants . . . . .	less than	1	gm of seeds	
" 2 plants . . . . .	" "	1.2	" "	"
" 1 plant . . . . .	" "	5.5	" "	"
" 1 plant . . . . .	" "	7.1	" "	"

On average 1.55 gm per plant

With the object of obtaining a vigorous, productive type both as regards forage and seed, the author decided to begin his work with material from *M. sativa* × *M. falcata*. Crosses can be effected easily without emasculation, all that is necessary is to adopt the usual method of applying the pollen by means of a brush to the flowers to be fertilised, after previous isolation.

The  $F_1$  hybrid has characters that are almost intermediate. Its shoots are more branched than those of *M. sativa* and its habit of growth more open, although not so decumbent as that of *M. falcata*. The colour of the flowers, which in the parents is bluish-violet and bright yellow respectively, becomes in the hybrid a dirty yellow, or greenish-yellow with more or less distinct violet-green veining. The pod is intermediate in shape between the sickle of *falcata* and the spiral characteristic of the common lucerne. Stolon development is more vigorous than in *falcata*, but less strong than in *sativa*. A second growth is rare but it is more vigorous than with *M. falcata* when it occurs.

The hybrid is superior in seed production to either of its parents.

In the  $F_2$ , very complicated segregation takes place. As regards stem length, some of the  $F_2$  hybrids have longer stems and some shorter than their parents; the habit of the hybrids is in most cases open as in the  $F_1$ , but some individuals have erect stems as with *sativa* and in other the stems are decumbent as with *falcata*. The colours are the same as in the flowers of the  $F_1$ , other shades such as light-yellow, violet-brown, bluish-violet and white being also found, all associated with the most various and complicated segregation phenomena.

There is not only an intermediate type of habit, but also of pod, as well as types similar to the parental, together with all possible intermediate forms and gradations.

It has been mentioned that the  $F_1$  produces abundance of seed; in the  $F_2$ , seed formation is not common and in certain individuals, completely absent. Some of the  $F_2$  hybrids are however very prolific, as is shown by Table I.

These data show that 378 out of 523  $F_2$  individuals or 72.3 %, produced less than 2 gm. of seed per plant; 111 or 21.2 % produced from 2 to 6 gm., 16 or 3 %, from 6 to 10 gm, 12 from 10 to 20 gm. and one plant only bore 39.8 gm.

In the  $F_2$  it is rare for the plants to shoot a second time but in this respect great variability is shewn.

TABLE I. — *Seed Production in the F<sub>2</sub> of Medicago sativa × M. falcata.*

Seed yield in grammes	Number of Plants					Totals	
	Line 37-1919	Line 38-1919	Line 39-1919	Line 40-1919	Line 41-1919	Plants	%

12.00-13.99 . . . . .	—	1	1	1	—	3	0.6
14.00-15.99 . . . . .	—	—	2	1	—	3	0.6
16.00-17.99 . . . . .	—	2	—	—	—	2	0.4
18.00-19.99 . . . . .	—	—	1	—	—	1	0.2
38.00-3.99 . . . . .	—	—	1	—	—	1	0.2
Totals . . . . .	10	260	191	34	28	523	100.0

Table II gives the forage yield.

TABLE II. — *Forage Yield of ordinary Lucerne and of the Hybrids of Medicago sativa × M. falcata.*

Kg. of green mass per hectare				
	1st cut	2nd cut	3rd cut	Total
Ordinary lucerne (Hungarian) . . . . .	31 750	22 350	13 250	67 350
<i>sativa falcata</i> (average of 16 Nos) . . . . .	35 000	7 000	1 500	43 500
" " No. 21-1919 . . . . .	43 000	7 500	2 000	52 000
" " " 32-1919 . . . . .	35 000	13 000	500	48 500
" " " 19-1919 . . . . .	19 000	2 000	—	21 000

The first cutting of the hybrid was slightly larger than that of ordinary lucerne, but the second and notably the third cuttings were distinctly smaller.

The author believes that it will be possible by means of continuous and systematic selection, in spite of the complications arising during segregation, to isolate cold-resistant types giving heavy crops of seed and forage, especially for the districts of Central Sweden where the inclemency of the climate precludes all hope of a third cutting. G. A.

401 — On the Origin of a new Line of Red Clover with short Corolla Tube. — LINHARD, E., in *Zeitschrift für Pflanzenzüchtung*, Vol. VIII, No. 2, pp. 95-120. Berlin, September 1921.

In 1907 NIELSEN observed in a clover field in Bohemia several plants with light-coloured flowers and relatively short corolla tubes. Among

the progeny of these plants, were individuals with pale flowers and short corolla tubes, which in 1911 produced two dwarf plants, all the organs being proportionally reduced in size: stems 10 to 15 cm. in height; flowers very small; capitula small and compact; corolla tube 4 to 5 mm. long. It was not possible to obtain seeds and to propagate this dwarf form. The experiments were continued with the family that had produced the dwarf type. In 1911, the author cross-pollinated two late plants with pale flowers and comparatively short tubes (8 mm.). By repeating the operation in the following years, he soon obtained a line with whitish (very pale violet) flowers true to colour, small compact flower-heads and short tubes. This new line was observed to be very accessible to bees, and the author therefore gave it the name of "Bienenklee", the Apitrefle of MARTINET, or bee clover.

The following Table gives in a comparative form the biometric data of the new line and of ordinary red clover.

*The Biometric Data of Bee Clover and common Red Clover.*

	Bee Clover	Common Red Clover	
	1920	No 38.46	No 50.33
Length of tube (in mm) . . . . .	6.91	9.99	(10)
Number » plants . . . . .	36	11	2
» » stems per plant . . . . .	13.3	21.0	31.5
» » flower-heads per plant . . . . .	233	253	314
» » » per stem . . . . .	17.5	12.1	10.0
» » seeds per plant . . . . .	8181	1745	935
» » seeds per inflorescence . . . . .	36	7	3.5
Total weight of plant, in gm. . . . .	145	173	306
» » of each plant, in gm. . . . .	17.6	3.4	2.5
» » of 1000 seeds, in gm. . . . .	2.14	1.90	2.65
» » of seeds in % of total weight. . . . .	11.8	2.0	0.8

This new line is not only distinguished by its relatively short corolla tube, but also by the large amount of seed it bears.

The short tube facilitates the entrance of the bees by which the clover is pollinated.

[G. A.]

402 - Experiments Researches on the Fertilisation of Red Clover (*Trifolium pratense*) in Germany. — SCHLECHT, F., in *Zeitschrift für Pflanzenzuchtunz*, Vol. VIII, Part 2, pp. 121-157. Berlin, September 1921.

This paper gives the results of experiments made at the Phytotechnical Station of Hohenheim, with a view to studying the problem of auto-sterility in red clover. The author in the course of his researches had also occasion to collect important data respecting the moisture of the air, the percentage of seeds that set, the presence of a new disease of the anthers and the occurrence of pods containing two seeds.

**EXPERIMENTAL CONTROL OF AUTOSTERILITY.** — For the purpose of isolation, gauze cages 30 × 30 cm. at the bottom and 80 cm. in height were used.

The operation was effected by exerting a slight lateral pressure upon the standard of the keel, so as to expose the stigma and the anthers. The pollen is collected on a brush and applied to the stigma; before passing from one plant to another, the brush must be dipped in alcohol to prevent any chance of cross-pollination.

The author only obtained a total of 10 seeds from 8589 flowers thus treated which may well have been the result of the involuntary introduction of foreign pollen: the autosterility of clover has thus once more been proved.

In order to confirm the results of the experiment, control tests were carried out on several flower-heads of the same plant, some being artificially cross-fertilised, while others were freely exposed to the visits of insects.

In both cases the percentage of seeds set was very high (from 32.8 to 68.5) thus showing that the operations had been very well carried out. It is clear therefore that the failure to produce seed mentioned above is to be attributed exclusively to autosterility.

When self-pollination (with the pollen of the same plant) is effected through the agency of *Bombus*, some seeds are usually obtained; this fact does not however discredit the theory of the autosterility of the red clover, for it is very difficult to find insects in the country that have not already been in contact with several clover plants.

**THE AGENCY OF INSECTS.** — Can bees act as pollinating agents? It is generally conceded that bees are not able to reach the honey of flowers with too long a corolla-tube. The author carried out 808 biometric determinations and obtained length values ranging from 5.2 mm. to 11 mm. The usual length was 8.9 mm. and the general average 8.7 mm. ZANDER reports that the bee can insert its proboscis to a depth of 7.9 mm.; if this is true, according to the author's statements, 72.5 % of the flowers of the clover would be accessible to bees.

In the control experiments, large gauze cages measuring 85 × 2000 cm. at the bottom and 100 cm. high were used.

The results are summarised in the following Table.

Mode of pollination	No. of inflores- cences	No. of flowers	Fruits set	
			No.	%
Bees . . . . .	125	11 692	6 328	53.2
<i>Bombus</i> . . . . .	100	9 517	4 516	47.5
Flowering in the open . . . . .	100	9 911	4 830	48.7
<i>Totals and averages . . .</i>	<b>325</b>	<b>31 120</b>	<b>15 584</b>	<b>50.1</b>

Thus the bee is as good a pollinating agent as *Bombus*.

EFFECT OF MOISTURE UPON POLLINATION. — Contrary to MARTIN'S conclusions, it would appear that a high degree of atmospheric moisture does not by itself interfere with the process of fertilisation.

TWO-SEEDED PODS. — Sometimes the two ovules produce two ripe seeds.

DISEASE OF THE ANTHERS. — The anthers of the red clover are occasionally attacked and destroyed by a fungus belonging to the genus *Botrytis*, but distinct from the species that are at present known. The author suggests for this fungus the name of *Botrytis antherarum-Trifolii*.  
G. A

403 - Genetic Behaviour of a New Seed Colour in *Trifolium pratense*, in Sweden. — WITTF, H., in *Svensk och Utsädesöfverens Tidsskrift*, Year XXXI, Part 6, pp 257-265. Malmö, 1921.

The colour of the seeds in clover varies considerably in different individuals, but is always uniform in the same individual. The colour-variations range through all possible shades from light yellow to purplishblack.

The author found in addition to these already well-known colours, another very rare hue, whitish-grey, or white, which had never before been observed.

This particular coloration of the seed always occurs in correlation with white flowers, lack of anthocyanin in the sepals and vegetative parts of the plant; we have therefore to do with an albino form. This character is recessive. In fact, if an albino individual is crossed with a normal, progeny with coloured seeds and white seeds respectively are obtained, in the second generation, in the monohybrid ratio: 3. 1. G. A.

404 - The Histological Characters of the Root of the Sugar Beet from the Point of View of Selection. — FLAHN, H., in *Zeitschrift für Pflanzenzüchtung*, Vol VIII, Part II, pp 195-205. Berlin, September 1922

Recently, the sugar-beet has been selected less with a view to sugar-content, than with the object of obtaining good root-development, in order to increase the amount of residue which forms an excellent stock-feed.

The present methods of selection, which are based on the polarisation and weight of the root, do not furnish sufficient data to serve as a guide in work directed to obtaining types with high yield and uniting in the best possible proportions both quantity and quality.

The larger size of a root is frequently due to its greater water content, and is not therefore transmissible. In determining the weight of the root it is therefore always necessary to consider the proportion between the water and the dry matter present. The latter alone is of importance from the standpoint of heredity.

In experiments in this type of selection, it would appear that the greatest difficulty is due to the negative correlation between the weight and the sugar content of the root. It is, however, not a question of true

correlation, but rather of co-ordinate dependence due to the fact that most heavy roots contain a large amount of water. This interdependence has been regarded as a basis for generalisation. In reality however types are to be found that combine a high sugar percentage with great weight of root, and the propagation of these types by means of pure lines has done much to show that sometimes the heaviest roots are also the richest in sugar. In selection therefore, as has been said, the dry matter must be taken into account. In the case of two beets of equal absolute weight, the more valuable from the genetic standpoint is the one in which the ratio: *water : dry matter* is lower.

This ratio provides the means of judging whether the tissues of the root are compact or not. The author gives the data for 10 roots. As regards the above ratio, it is possible to distinguish, taking 2.75 as the mean, 6 roots with compact structure (I-III-VI-VIII-IX), with values ranging between 2.71 and 2.61, and 4 roots with loose structure (II-IV-V-X) with values between 2.77 and 2.92. Some excessively large roots (like II-IV-V), weigh a great deal (763-651-560 gm.) but their structure is far from compact (2.92-2.85-2.90); from the genetic standpoint they cannot be regarded as actually heavy.

If a comparison is made between Nos. II and III as regards weight, we find:

Root No. II weighs 763 gm and contains 194.56 gm. of dry matter and 568.43 gm. of water in the ratio of: 1 : 2.92.

Root No. III weighs 684 gm. and contains 188.44 gm. of dry matter and 495.51 gm. of water in the ratio of: 1 : 2.63

Differ: in favour of II: + 79 gm. + 6.12 gm. of dry matter + 72.87 gm. of water in the ratio of: 1 : 11.91

The 79 gm. difference in weight is largely due to a greater amount of water. In order to have equivalence, instead of 6.12 gm. of dry matter and 72.87 gm. of water, 21.75 gm. and 57.25 gm. respectively should have been found.

In estimating the actual value of two beets (again taking as a basis of comparison root No. II), the following equation was obtained:

$$763 \text{ gm (weight of root): } 194.56 \text{ (dry matter) } = 684 : x \\ x = 174.41 \text{ gm. of dry matter.}$$

As a matter of fact, root No. III which weighed 684 gm., contained 188.44 gm. of dry matter, that is to say, 14.03 gm. more.

In the same way, although root No. II with 79 gm. more weight might be considered equal to No. III, it would be necessary, if this were the case, for the weight of 763 gm. instead of being made up of 194.46 gm. of dry matter and 568.43 gm. of water in the proportion of: 1 : 2.92, to be made up of 210.19 gm. of dry matter and 552.81 gm. of water in the proportion of: 1 : 2.63.

Thus beetroot No. II contains 15.63 gm. of dry matter + 15.62 gm. of water and its value is therefore lower than that estimated for beetroot No. III.

If the dry matter content of these roots is calculated in this manner and the average taken as 141.87 the following values are obtained :

No of roots	Actual Value	Proportional Value	Difference
	gm.	gm.	gm.
I . . . . .	214.65	212.00	+ 2.65
II . . . . .	194.56	203.47	— 8.91
III . . . . .	188.44	182.40	+ 6.04
IV . . . . .	168.93	173.60	— 4.67
V . . . . .	145.52	151.47	— 5.95
VI . . . . .	117.54	116.27	+ 1.27
VII . . . . .	102.98	99.47	+ 3.51
VIII . . . . .	102.43	98.93	+ 3.50
IX . . . . .	98.55	94.67	+ 3.88
X . . . . .	85.13	85.60	— 0.47

Therefore the 6 roots with compact structure come in the following order III — IX — VII — VIII — I — VI.

On the other hand if we apply von RÜMKER's correction for the ratio between weight and sugar content and take as a basis of comparison the average weight of a root weighing 532 gm. with 20.72° of polarisation we obtain for root I :

Weight of root I	= 795 gm	
Average weight of all the roots	= 532 gm	Corresponding polarisation = 20.72°
Difference in favour of No. I	= + 263 gm	von RÜMKER's correction = 0.77°
		Corrected polarisation = 19.95°
		Polarisation of root No I = 19.10°
		Difference . . . . . = 0.85

For the more compact beetroots, the following values are obtained.

IX = 1.61; III = 1.25; VI = 0.63; VII = 0.14; VIII = 0.09.

The results of determining the dry matter on the one hand, and the weight of the root and the polarisation angle on the other, do not agree. Therefore, the present methods of selection, which are based on the polarisation and weight of the root, cannot yet be considered as satisfactory.

The polarisation data must be corrected by the sugar content of 100 parts of dry matter, and the structure and absolute weight of the root should also be taken into account .

#### SEEDS

405 — **A Bio-Chemical Index for Determining the Vitality of Seeds** (1). — NEMEC, A. and DUCHON, F., in *Comptes rendus de l'Académie des Sciences*, Vol. 174, No. 9, pp. 631-634. Paris, February 1922.

The authors have shown (*Comptes rendus* Vol. 173, 1921, p. 933), that the activity of the catalyst affords a rapid and easy means of determ-

(1) See *R. March* 1922, No. 253. (Ed)

ining the vitality of seeds. They adopted the following method : 2 gm. of finely ground seeds are mixed with 20 cc. of distilled water and put into a flask with a rubber stopper provided with two holes through one of which passes a funnel with a regulating tap, while an escape tube with two bends passes through the other and thence into a vessel of water and under a gas-bell graduated to tenths of a cubic centimetre. By means of the funnel are introduced 15 cc. of 3 % oxygenated and neutralised water and the amount of oxygen liberated is measured after 5 minutes, and later after 15 minutes.

The results of many experiments have demonstrated that all other factors being equal, the amount of water decreases regularly with the weakening of the germinative capacity.

These results expressed graphically give a regular curve and thus the germinating power of the seeds can be deduced from the amount of oxygen liberated.

In practice, it is well to use the comparative method, and to compare the catalytic activity of the ground seeds under examination with the graphic curve obtained under the same conditions from seeds of known germinative power.

P. C.

406 - **The Exportation of Red Clover Seed from Czecho-Slovakia.** — *Bulletin of the Ministry of Agriculture of the Czecho-Slovakian Republic*, Vol. III, No. 1, p. 8. Prague, January 1, 1922.

The seeds of forage crops, especially those of Red, White, Swedish and Crimson Clovers (after which comes the seed of Sainfoin etc.), are among the most important agricultural products exported from Czecho-Slovakia. Statistics show that the following quantities of clover seed were produced in 1920 : in Bohemia, 121 098 quintals ; in Moravia 45 157 quintals ; in Silesia 3 341 quintals, in Slovakia, 34 993 quintals ; in Sub-Carpathian Russia, 2895 quintals ; the total production amounting to 207 484 quintals. Owing to its excellent qualities this seed finds a ready market abroad, especially in England, Scandinavia etc. In 1921, about 300 trucks of red clover seed were exported. There are certain restrictions on its exportation, for as adverse climatic conditions have damaged the clover crops in Czecho-Slovakia, the Government has been compelled to limit the consignments of clover seed sent abroad, in order that the farmers may have sufficient for their own requirements. On the other hand, the Experiment and Seed Testing Stations are protecting the reputation of Czecho-Slovakian clover seed by guaranteeing its purity, power of germination, and freedom from any admixture of weed seeds.

407 - **Steady Decline in Price of Vegetable Seeds in the United States since 1918.** — *Weather, Crops and Markets*, Vol. I, No. 7, p. 129-146. Washington, D. C., Feb. 18, 1922.

Prices quoted for vegetable seeds, both by retail mail-order and wholesale dealers in the United States, are almost uniformly lower than in 1921, and, for most items, the lowest since 1917. The decline has been constant since 1918, when the peak was reached for most kinds. The accompanying table of retail catalogue and wholesale prices show that the prices of beans,

peas, sweet maize, lettuce, and vine-crop seeds fluctuated less violently than did other seeds, including beets, cabbage, celery, spinach, and turnip, of which large quantities normally are imported.

*Average Wholesale (Wh) and Retail Catalogue (R) Prices of Standard Varieties of Vegetable Seeds (\$per pound)*

\* Not including Lima beans.

Any changes in the price of the former group, of which the domestic production is usually sufficient to supply the needs of the United States, may be attributed largely to variations in the cost of production and preparation for market. The supply of the latter group, however, was not controlled by domestic commercial growers and with imports suddenly cut off, the high prices prevailing in 1918 followed. Likewise the rally of domestic growers to supply the deficit thus created, followed by the rapid resumption of imports, caused these items to decline quickly to their 1917 price levels.

On the whole, wholesale prices for 1922 compared with 1921 show a greater reduction than do the retail catalogue prices. The wholesale prices of beans, peas, sweet maize, beet, cabbage, carrot, celery, onion, parsley, squash, and turnip are 15 %-30 % less while the retail-catalogue prices of these items, with the exception of cabbage and English turnip, are only 5 %-15 % less than last year. Very little change, if any, occurred in the

wholesale prices of other kinds of vegetable seeds except tomato which is quoted 10 % less. The average retail prices of tomato declined 8 %, spinach 15 % and watermelon 9 %, cucumber, lettuce, muskmelon, parsley, parsnip, and radish were unchanged to slightly lower.

408 - Reliability of the Nail Test for predicting the Chemical Composition of Sweet Maize. — APPLEMAN, C O (Maryland Agricultural Experiment Station), in *Journal of Agricultural Research*, Vol. XXI, No. 11, pp. 817-820, Washington, September 1921.

CEREALS  
AND  
PULSE CROPS

In carrying out the nail test, the thumb-nail is thrust into the kernel, and the exudate examined which is opalescent, milky, creamy and doughy in the 4 successive stages of ripening, at the last stage, the kernels begin to turn yellow.

The author made parallel and comparative experiments with sweet-maize and found from the results of chemical analyses of the kernels that the nail test was reliable, although its reliability is influenced by the rate of ripening and of water loss by evaporation.

He also discovered that

The corresponding stages of crops ripening under different climatic conditions vary both in uniformity of composition and average percentage composition.

The percentage composition of the carbohydrates in the milky stage of a late crop was much more uniform than in the same stage of an early crop.

The nail test is most reliable when applied to crops that ripen slowly in a cool autumn.

In each of the ripening stages except the dough stage, the percentage of total sugar was more constant than the percentage of starch.

As ripening proceeds, the increase in the percentage of starch is much greater than can be accounted for by the decrease in the percentage of sugars. From the beginning of kernel formation until the end of the ripening period there is a continual movement of sugar from the plant into the kernels where it is transformed into starch. The following Table gives the average percentage of the composition of kernels of sweet maize of a late and early crop respectively, as indicated by the nail test. The percentages are calculated with reference to the dry matter content.

*Percentage Composition of Sweet Maize at Different Stages of Ripening*

Crop	Pre Milk Stage		Milk Stage		Early dough Stage		Dough Stage	
	Total sugar	Starch	Total sugar	Starch	Total sugar	Starch	Total sugar	Starch
Early	42.013	22.080	29.183	38.911	13.515	56.519	8.786	59.422
Late	51.200	24.080	35.297	33.475	15.328	50.975	—	—

409 — **Rice in the Philippines.** — CAMUS, J. S. (Agronomist in Charge of Agronomy Section) in *Government of the Philippine Islands, Department of Agriculture and Natural Resources, Bureau of Agriculture, Bulletin No. 37*, pp. 1-87, tables 10, pl. XLVII. Manila, 1921.

The author gives detailed information as to the climatic conditions, soil and cultural operations associated with rice growing and the cost of production, preparation of grains for the mills and utilisation of by-products, and describes the latest tests and experiments conducted by the various Philippine Experiment Stations especially with reference to varieties, selection, etc.

This bulletin was prepared primarily as a practical guide to the ordinary rice grower of the Philippines, but as it is based on 11 years of experimentation by the Bureau of Agriculture, it is also of fundamental interest to the scientific agriculturist. Certain points of special interest have here been selected.

1) **TYPES OF GRAINS AND VARIETIES** — The commercial varieties of grain measure usually 2.5 mm.  $\times$  5.5 mm., but vary considerably in shape and also in colour. The varieties used for general consumption belong to the non-glutinous group.

Experiments made with a view to the selection of improved varieties of lowland rice (transplanted) have been conducted at the Alabang and Pangasinan Stations, and of upland rice (non-transplanted) at La Carlota and Linao. Data with reference to habitat, age at heading, maturity and yield for each variety were taken and careful records kept of the best varieties determined.

Most of the lowland varieties tested have shown a comparatively limited range of yields, which will necessitate further trials for some time. Except for timing the planting and harvesting to profit by the average weather conditions, it is not considered advisable to grow a variety that requires more than 150 days to mature. The Apostol (originally known as Señora II) was found to be one of the best varieties and its characteristics may be summarised thus: number of days required from sowing to heading 112, from heading to maturity, 32; yield per hectare 23.83 kg.; shape of grain, somewhat thick, linear oblong, breadth 2.98 mm., hull straw coloured, medium thickness, non-bearded, cuticle white; average length of head at harvest 29.5 cm., average number of grains per head 151; flavour medium.

The 44 most promising varieties out of 282 have already been improved by means of the head-to-row test. Pure strains of these varieties have been isolated, propagated and the seed produced was distributed throughout the Philippines. The varieties tested thus were: Apostol, Cruz, Inasimang, Macan I, Piniling, Daniel, Comer and Roxas. The average yield was 26.48 kg. per hectare; the first four matured earlier than the last three, all of them are non-glutinous and non-bearded.

As regards the Upland varieties out of the 431 tested, the following 11 are recommended for general planting. — Bagonhon II, Binicol I, Catalong, Dinagat I, Inantipolo II, Kinandang Puti II, Kinastila IV, Nagdami, Nagsaya, Pulupot and Saloot. Of these the Kinandang Puti II

matured earliest (106 days). The average yield for these 11 varieties is 22.56 kg. per hectare ; all are non-bearded.

As a result of all the breeding experiments undertaken, it has been shown that by using selected seed the production of rice has been almost doubled.

**SOILS AND MANURES** — In the best rice producing provinces such as Nueva Ecija, Pangasinan, Tarlac, Bulacan etc., most of the soil consists of a heavy clay containing 20 % fine silt and 40 % clay with an adequate supply of humus. This type of soil however has been found advantageous to lowland varieties rather than to upland which require a good loam.

There has been much difference of opinion as to the use of commercial fertilisers, but experiments in the Philippines have shown that a ratio of 5 % nitrogen, 8 % phosphoric acid and 10 % potash is advisable and ammonium sulphate has been found the best form of nitrogenous fertiliser.

**CULTURAL METHODS.** — A description is given of the 5 general methods of planting viz. "cañing" or mountain, dry or upland, "sabog" (palay broadcasted on the rice paddies), and tubigan (lowland).

As regards the methods of seedbedding the, "dry seedbed" method has been proved unsuitable, but the ordinary seedbed method (transplanting 30-40 days from sowing previously sprouted seed) has given good results, and also the so-called "dapog" system of covering with banana leaves by which it is possible to transplant seedlings at a much earlier stage than with the ordinary method. The ordinary system requires on an average 60 to 75 lb. of seed to plant a hectare and the dapog system 15 to 30 lb. more. This latter system is recommended for places where the palay is broadcasted on the paddies or where the planting season is well advanced. It is also advisable in growing early-lowland rice varieties during the regular season.

**CROP ROTATION.** — Although this is not usually practised, the planting of maize or beans especially the mungo (*Phaseolus mungo*) is advised.

**DISEASES AND PESTS.** — Until crop rotation, etc. is practised, the difficulties of controlling the locusts and cutworms (*Prodenia litura* and *Spodoptera mauritia*), rice bugs (*Leptocoris acuta*) etc. are bound to exist.

**COST OF PRODUCTION.** — The following estimates of the cost of production per hectare of the lowland, upland and tenant systems are based on the average cost of labour and actual experiments conducted at certain stations.

From the above estimates and calculating on the average for the 1919 crop of 24.48 cavans per hectare, the cost of producing 1 cavan of palay, taking the average of the 3 methods of planting, will be pesos 2.83 and pesos 5.66 for clean rice. The value of by-products will cover the cost of milling. It is estimated that 100 kg. of palay produce about 62 kg. of clean rice ; 18 kg. of meal or broken grains, 14 kg. of hull and 6 kg. of "bran".

*Estimated cost of production of rice per hectare. 1920.*

- 410 - **Rice-Growing in Messenia, Greece.** — GARDIKIS, J. J. (Departmental Agriculturist of Messenia), in *l'Economiste d'Athènes*, 1st year, No 18, pp 278-279. Athens, January 19-1 February 1922

Rice-growing was introduced into Messenia in 1919 by the Departmental Bureau of Messenia. A preliminary trial was made on 45 *stremmes* (4500 sq. metres). The total crop obtained was 2500 kg of paddy. Next year, 1500 *stremmes* were sown, the yield for 1200 of which was 375 000 kg.

Rice cultivation has attracted the attention of the Government, and the National Assembly passed at its first reading a Bill granting a sum of 100 000 drachmas for the encouragement of the industry.

Messenia rice is superior as a food to the rice imported from abroad. Rice-growing could easily be extended to an area of 13000 *stremmes*, and with careful management of the water-supply which is sufficiently large, this area might be increased to 30 000 *stremmes* and the production might reach 15 000 tons with a value of 48 million *drachmas*.

Great advantages would accrue to the country from rice cultivation, which would be a source of wealth and bring about 350 000 *drachmas* into the Treasury in the form of State taxes. The regulation of the river Pamissos would contribute to the extended cultivation of other crops while the drainage of the Messenian swamps would free the country from malaria.

- 411 - **What Amount of Phosphatic Fertiliser is necessary for Rice?** — NOVELLI, N. in *Giornal di Ricoltura*, Vol XII, No 2, pp 20-22 Verelli, February 28, 1922

The author had analysed at the Laboratory of Agricultural Chemistry of the Royal Agricultural College in Milan, a sample of "Chinese originatio" or "Abbondanza", a variety of rice which, together with other very similar types, is the kind most widely cultivated in North Italy. The straw was found to contain 0.40 % of phosphoric acid and the paddy 0.90 %. As the paddy and straw yield per hectare can be reckoned respectively at 60 quintals and 90 quintals, about 90 quintals of phosphoric acid (a substance in which most of the soils of the Italian rice-fields are generally poor), are removed by the crop. The analyses made by the author have shown that few soils contain more than 1 per 1000 of phosphoric acid; the best rice-field soils contain from 0.5 to 1 per 1000. Further the irrigation waters of the principal rice-growing districts of Italy are practically entirely deficient in phosphoric acid, which has therefore to be entirely restored to the soil by the manure.

Leaving a small margin to cover losses, this must be applied at the rate of at least 7 to 8 quintals per hectare of phosphatic fertiliser containing 15 % soluble phosphoric acid,  $\frac{2}{3}$  of which should be harrowed in before the rice-field is flooded, and  $\frac{1}{3}$  after the first weeding, when the rice-field is dried. For the application of the nitrogenous fertilisers, this being a larger amount than is generally used. The author calls attention to the troubles arising from an insufficient quantity of phosphatic fertiliser; late ripening, susceptibility to disease, defective fertilisation and seed-setting.

- 412 - Additional Notes on Adlay (*Coix Lacryma-Jobi* var. *mayuen*), in the Philippines (1). — WESTER, P. J., in *The Philippine Agricultural Review*, Vol. XIV, No. 2, pp. 159-177. Manila 1921.

The previous article (1) with reference to the general cultivation and commercial value of the adlay (*Coix Lacryma-jobi* var. *mayuen*) was written before the actual milling and baking tests had been made. The author here reports the information since accumulated.

It has been demonstrated that adlay forms a palatable and wholesome food and according to the data collected it appears that a mixture of equal parts of adlay and wheat flour or  $\frac{2}{3}$  adlay to  $\frac{1}{3}$  wheat, would be equivalent for all practical purposes to an equal quantity of wheat flour, except that it is slightly richer in fat. The nutrient value of adlay in comparison with other cereals and pulse crops is of decided interest: adlay (average of 8 samples tested) 95.4, wheat 87.4, maize 91.2, rice 88.3, oats 80.6.

The great advantage of adlay over rice is that it is possible to grow and harvest with machinery, which is impossible for rice paddies.

With lowered cost of production and an improvement in quality of grain etc, adlay would appear to be destined to supplant rice as the leading staple grain over considerable areas.

The previous rejection of adlay as a staple food may be attributed to peculiar features which have made it inferior to rice as grown by a primitive people, rather than to any intrinsic inferiority in the grain. The advent of modern machinery etc. has removed these objections.

It is interesting to note also that although the long growing season is admittedly a drawback, this is balanced by the fact that adlay is less subject to attacks of locusts than rice and maize and the rice bird and wild pigeon also appear less destructive. This is true also of the rice bug *Lep-tocoris acuta*, one of the two most destructive insect pests of the rice plant.

M, L. Y.

- 413 - Alimentary Value of Some Indo-Chinese Leguminosae. — PRUDHOMME, R., in *L'Agronomie Coloniale*, Bulletin mensuel de l'Institut National d'Agronomie Coloniale, Year 6, No. 5, pp. 33-41. Paris, February 1922.

The author, after referring to the importance of the importation of dried vegetables from the Colonies to France, describes the various Leguminosae cultivated in Indo-China:

1) PURPLE DOLICHOS (Dâudo) (*Dolichos* var. undetermined) — Its chemical composition is as follows: Water 11.98%; ash 2.86%; fatty substances 1.10%; nitrogenous substances 24.08%; sacchariferous substances 41.8%; crude fibre 6.72%. The natives cook it like ordinary rice; it can be compared to kidney-beans, lentils and common vetches.

2) FRENCH BEAN (Dâu-xanh) (*Phaseolus radiatus*). — This is much the most important of all the Leguminosae. Its chemical composition is as follows: Water 12.10%; ash 3.12%; fatty substances 0.64%; nitrogenous substances 25.40%; sacchariferous substances 42.86%;

(1) See R. June 1921 No. 625. (Ed.)

crude fibre 7.84 %. When ground it is used in Annam for making a kind of vermicelli (known by the name of « Songthân »; about 80 000 kg. of which are manufactured and exported to China. This vermicelli differs greatly from that consumed in Europe. It contains a much smaller quantity of nitrogenous and fatty substances but its crude fibre content is higher. Further its composition varies greatly in different samples. The vermicelli contains 25 % less nitrogenous and mineral substances and much more sacchariferous substances than the beans from which it was made.

These beans are much appreciated as a vegetable after germination, and are eaten when the stalks are from 8 to 10 cm in length. They are a common article of diet among the European population of Indo-China. They crop easily if previously soaked in water for about 12 hours (after which they cook in 40-60 minutes). When boiled they much resemble lentils and have a clean pleasant taste. This *Phaseolus* presented on analysis only slight traces of glucosides, it is entirely free from cyanogenetic glucosides, alkaloids, and glucosides poisonous to mice.

3) SPOTTED DOLICHOS (Dâu-truong-quôc) (*Dolichos tonkinensis*); Chemical Composition Water 11.02 %, ash 3 %, fats 1.34 %; nitrogenous substances 23.35 %, sacchariferous substances 38.30 %; crude fibre 8.96 %

VIGNA SINENSIS (Dâu-den-kouta-long) — Chemical composition: Water 12.14 %; ash 3.08 %; fats 1.14 %; nitrogenous matter 24.5 %; sacchariferous matter 43.36 %; crude fibre 7.92 %

WHITE DOLICHOS (Dâu-trang) These three beans can be used in the same manner as the purple Dolichos. All of them need 120 minutes boiling after soaking for 12 hours. They are superior in quality to our ordinary French beans, but not as good as *Ph. radiatus*. Their use is to be commended both as an article of human diet and as a cattle feed.

4) SOY-BEAN — This is a well-known plant and is only mentioned by the author.

To sum up, *Phaseolus radiatus* is the species most suitable for human consumption, though the purple, black and spotted varieties of Dolichos can also be used. The white Dolichos and the soy-bean are chiefly fed to stock.

414 — The new Chinese Variety of Lucerne in South Africa. — DONKIN, J. L., in the *Journal of the Department of Agriculture Union of South Africa*, vol. III, No. 3, pp. 257-258 Pretoria, Sept. 1921.

FORAGE CROPS

FAIRCHILD, the "Agricultural Explorer" of the United States Department of Agriculture, found in Thibet, at a height of about 1200 feet above sea level, a new variety of lucerne growing on the edge of a swamp. This variety has been tested for a period of five years at the School of Agriculture of Grootfontein near Middleburg, Cape Province, where for purposes of comparison it has been grown side by side with six other well known types.

Although during the first period of growth this "Chinese" variety as it has been called, could not be considered as equal to the "Provence"

and "Tamworth" types, owing to thin seeding in the two last years of the test it gave hay crops almost equal to those of "Provence" and superior to those of "Tamworth". Observations taken seem to show that "Chinese" lucerne is a hybrid and several variations in stalks and leaves etc. are noted. It is a heavy cropper and particularly resistant to frost.

If grown for seed, 1 oz. is sufficient for a row 100 yards long, which in the second year should produce enough seed for one acre; this should in turn produce a sufficient quantity of seed for sowing broadcast several acres every year.

M. L. Y.

415 - Experimental Trials in Natal with "Hubam Clover" a new Variety of *Melilotus alba* var. *annua*. — HAIL, W S, in *Journal of the Department of Agriculture, Union of South Africa*, Vol III, No 5, pp 463-465. Pretoria, Nov. 1921

The utility of the annual white sweet clover (*Melilotus alba* var. *annua*) as a forage crop and as a legume in short rotations has been the subject of much attention lately in the United States and in Canada.

The Iowa strain of seed, introduced by H. D. HUGHES of Iowa University, has recently been tested at the Cedara School of Agriculture and Experiment Station, Natal (S A), and the variety known as "Hubam clover" has proved a distinct success.

The plant is recommended as a forage crop, but stock should not be allowed to pasture immediately after rain or heavy dew. Although some animals do not appear at first to appreciate its bitter aromatic taste, they soon acquire a liking for it if fed constantly on Hubam clover. Its feeding value compares favourably with other legumes.

In appearance, "Hubam clover" resembles the biennial form of melilotus except that it is somewhat smaller, the root is more woody and crown or resting buds are not formed. The stems, branches, leaves, flowers, pods and seed are indistinguishable from the biennial form.

It has been ascertained by tests made in the United States that the percentage of biennial plants raised from annual seed varies from 1 to 8.

The seed possesses a hard coat and consequently germination is slow unless the seed is scarified and thus enabled to absorb the necessary moisture more readily. Scarified and unscarified seed give a germination percentage of 90 and 30 respectively. A special machine has been invented at the Iowa Agricultural College for this purpose known as the "Ames Hulling and Scarifying Machine".

Soil moisture is necessary; only moderate results are obtained on acid soils, although rather more satisfactory than is the case with lucerne; better results are obtained on alkaline soils.

When the plant reaches a height of 30 in. before the blooming period, it may be cut and cured as hay though it is essential to preserve the leaves carefully. As soon as the plant is wilted, cocks should be made immediately, and left until the stems are cured. It may be ensiled if cut in the early stages before the stems have become woody.

Further tests are being carried out in order to ascertain the agricultural value of this plant in South Africa.

M. L. Y.

- 416 - **Cotton-Growing in Algeria** (1). — FOURNIER (Head of the Experiment Station at Ferme-Blanche, Oran), in *Revue agricole de l'Afrique du Nord*, Year 20, No. 128, pp. 26-29, 2 photographs. Algiers, January 13, 1922.

The author gives an account of the results obtained on the estate of Habra and de la Macta, near Perrégaux. In 1910 the average cotton crop was 13.8 quintals per hectare, which represents about 4.5 of cotton fibre for the varieties Yanovitch and Abassi. The net profit was 745.65 fr. per hectare.

The 1920 results are distinctly higher: the "Yuma" and "Californie" early varieties derived from the Egyptian variety, "Mitafifi", produced over 23 quintals of unginned cotton per hectare. The later-maturing varieties on the neighbouring estates only produced 5.5 quintals per hectare. The land of the Experiment Station had been dressed with 40 quintals of well-rotted dung and 40 quintals of bat guano per hectare.

The pickings succeeded one another without interruption from August 26 to the end of November.

The receipts per hectare were 7068.80 fr. and the expenses 2 525.85 fr. Therefore the net profit was 4 544.95 fr. per hectare, or 6 times larger than in 1910.

At the present time there are 300 hectares under cotton in the Orléansville district.

The varieties selected by Dr. TRABUT, Director of the Botanic Service, Professor of the Agricultural Institute of Algeria, produce bolls that can be gathered before the heavy rains set in. Their yield is satisfactory, and they are much earlier than "Yuma," or "Californie". The author adds that the cotton-plant can bear relatively large quantities of salt. P. C.

- 417 - **Irrigation Schemes in the Niger Territory of the French Soudan and the Extension and Improvement of Cotton Production.** — I. LELUC, J., *Le coton du Soudan et les grands projets d'irrigation in L'Avenir Textile*, No. 9, pp. 9-11 Guebwiller (Haut-Rhin), July 1921. — II. HÉLO (Secrétaire général du Comité du Niger), *Les irrigations du Niger et la culture cotonnière au Soudan, in Renseignements Coloniaux et Documents publiés par le Comité de l'Afrique française et le Comité du Maroc*, pp. 127-220 Paris, Oct. 1921.

I. II. — Up to the present time cotton has been cultivated in the French Soudan over an area of more than 150 000 sq. km., but the irregularity and short duration of the local rains has resulted in inferior quality fibre and poor yield. With the object therefore of introducing and developing varieties with medium and long fibres and extending the cultivated area, schemes have been put forward to systematise and establish regular irrigation and the utilisation of the floods of the river Niger which occur at a time of year propitious to cotton development. For example, during 200 days (June to January), the Niger distributed more than 400 cub. m. per second, and it is estimated that this would serve to irrigate a cotton area covering from 400 000 to 500 000 hectares *i. e.* 1 200 000 to 1 300 000 hectares on a triennial rotation system.

(1) See *R. Mar.* 1917, No. 243; Aug. 1918, No. 865; Oct.-Dec 1919, No. 1138. (Ed.)

According to the remarkable Scheme prepared by the hydraulic expert BÉLIMF, it will be possible to obtain as a result of methodically established irrigation, first quality cotton ranking with the best known varieties, Sakellaridis etc., as well as remunerative yields. It is a recognised fact that Cambodia, Algeria and Senegal etc. yield a considerable quantity of cotton, but it is now considered evident that the most valuable area will be in the Niger valley.

The authors give an outline of the programme of proposed irrigation work, the lines of canals etc

M L Y.

418 - **Cotton Growing in Queensland.** — BOYD A. G., in *Queensland Agricultural Journal*, Vol. XVII, Pt. 1, pp. 32-34. Brisbane, Jan. 1922.

Distinct advances have been made quite recently in connection with the extension of the cotton areas in Queensland. Very favourable reports as to the future possibilities of this country, have been presented by VAUGHAN (Ex-Premier of South Australia) who states that the British Government has set aside a sum of £1,000,000 for the encouragement of cotton-growing within the Empire, a portion of which would be devoted to the establishment of the industry in Queensland. Up-to-date machinery (cotton gins etc.) has been imported for use with the next crop, which is expected to be a comparatively heavy one.

A short time ago VAUGHAN secured cotton samples from different districts and submitted them to English cotton brokers for inspection. Opinion was unanimous that the samples possessed all the best qualities of the more valuable cottons of other countries (probably including America, Egypt, Africa and India), in respect of length, strength of fibre, colour, etc.

Up to the present, practically all the inland areas have been cultivated with the Uplands variety (short staple), and the Sea Island type has been limited to coastal areas. It is proposed however to use Sea Island to a much larger extent inland next year, as the long-staple is of great commercial value.

An important point in favour of Queensland as a cotton producer is that the plant is almost entirely free from the diseases which cause so much damage in the cotton districts of the United States and Egypt.

419 - **New Fibre Crops in the Belgian Congo, and their Industrial Value.** — GOOSSENS, (Directeur du jardin botanique d'Étala), in *Bulletin Agricole du Congo Belge*, Vol. XII, No. 3, pp. 622-623. Brussels, Sept. 1921.

The Jardin botanique d'Étala has recently carried out a series of observations under the direction of CORNUSIER with a view to ascertaining respectively the values of various fibre plants, both native and imported.

The annexed Table shows the results of the investigation. It is stated that although the imported varieties do not appear to adapt themselves readily to equatorial conditions, excellent results have been obtained in the Lower Congo (Ganda-Suudi and Congo da Lemba).

## Results of the Cultivation of Textile Plants in the Belgian Congo.

	Name of plant	Weight of stems	Period of retting	Weight of fibre	No of days of work	Time required to produce 1 kg. fibre	Net cost 1 kg. fibre	Yield
		kg	days	kg.	days	days	fra.	%
Native	<i>Urena lobata</i> var. <i>reticulata</i> (Kuluende) . . . . .	615.3	15	49.88	57.00	1.15	0.86	7.95
	<i>Urena lobata</i> (Lotiti muindu) . . . . .	638.4	20	36.00	58.87	1.68	1.26	5.64
	<i>Triumfetta cordifolia</i> (Bekongue) . . . . .	1517.5	15	70.235	70.8	1	0.75	4.61
	<i>Cephalonema polyanthum</i> (N'dolo n'kongue) . . . . .	1580.0	20	76	83.7	1.10	0.82	4.81
	<i>Honckenia ficifolia</i> (Bonkongue n'inga) . . . . .	666.5	22	33.280	111.3	3.34	2.50	5.00
	<i>Mannisphyton africanum</i> (N'kossa) . . . . .	785.0	—	25	134	5.36	4.02	3.18
Imported	<i>Agave rigida</i> var. <i>sisalana</i> . . . . .	300.0	—	11	65	5.90	4.42	3.66
	<i>Furcraea gigantea</i> . . . . .	880.0	—	14	120	8.57	6.42	1.50
	<i>Sansiviera guineensis</i> . . . . .	14.0	—	0.190	—	—	—	1.35
	<i>Sansiviera cylindrica</i> . . . . .	14.0	—	0.150	—	—	—	1.07

The stems of *Mannisphyton africanum* are not retted, but they are scraped immediately after cutting, and exposed to the sun, and after a few days, the fibre is extracted by thrashing.

It has been noted that the period of retting is regulated according to the stage of maturity of the stem, the type of soil also plays an important part in this process.

Although the actual quality of the fibre is not of equal value to that of the imported species, attention is drawn to the fact that certain native species, especially *Urena lobata*, can be utilised advantageously as a source of fibre at a comparatively low cost.

120 - The Possibilities of Developing the Roselle (*Hibiscus Sabdariffa* var. *altissima*) Fibre Industry in the Federated Malay States. — SOUTHERN, F. W., in *The Agricultural Bulletin of the Federated Malay States*, Vol. IX, No. 1, pp. 23-26. Kuala Lumpur, Jan-Mar 1921.

As a result of the small scale experiments carried out by MATHIEU at Kuala Kangsar, with *Hibiscus Sabdariffa* var. *altissima*, the following conclusions may be drawn:

This plant appears to adapt itself readily to prevailing conditions in the Federated Malay States.

The lateral branches when cut at the right age (i.e. when the plants are just beginning to flower and when if properly developed, the branches should be over 4 ft. long), should give a good quality long staple fibre, suitable for spinning. Reports from the Imperial Institute, London

confirm this statement. On the other hand if the branches are cut when too old, the fibre is found to be matted and consequently of inferior quality.

Fibre from the *main* stem is however of inferior colour, appearance and quality and the staple is shorter and is in fact of no value commercially.

The plants seed fairly freely but are liable to attack by the cotton stainer *Dysdercus* spp.

Further experiments are in progress to determine the best planting distances to adopt, and also to obtain a large supply of seed of both the red and the green varieties. Seed is being distributed to various plantations for test purposes.

The work in general is as yet at an early stage and investigations are still necessary with reference to cost of production, methods of cultivation etc.

**RUBBER, GUM  
AND  
RESIN PLANTS**

421 — The Quality of the Rubber of *Hevea brasiliensis*: its Variations and their Causes. Economic Importance for the Amazon Rubber Industry. — CAYLA V (Professor of General Agriculture) in *Archivos da Escola Superior de Agricultura e Medicina Veterinária*, Vol V, Nos 1 and 2, pp 71-96 Niteroy (E. do Rio), Sept. 1921

A factor frequently introduced into the very complex question of rubber production, which is of paramount importance to Brazil, is the quality of the product, that is to say its market as apart from its intrinsic quality.

For manufacturers or producers, there is nothing absolute in the quality of rubber which can however be determined scientifically from its physical and chemical constants, as has been shown by the valuable, exhaustive and accurate laboratory experiments systematically made by the Dutch since 1910.

Hitherto the commercial determination as carried out, for instance, by the brokers has been accepted. This determination was based on external characters: form, appearance of surface, colour, smell, appearance of a single section, elasticity determined roughly by pulling a sample between the hands etc. These observations can only furnish very incomplete information, and are useful only to expose 1) the grossest frauds, 2) the state of the preservation of the rubber, 3) its geographical origin.

The quality of rubber can be approximately determined by: 1) the quantity of coarse, visible impurities (decrease in useful weight); 2) the presence or absence of diseases: moulds, and especially stickage, which causes bad vulcanisation, 3) the knowledge acquired by long experience of the various kinds of crude rubber according to their origin, botanical source, processes of coagulation, drying etc.

In scientific determination, the Dutch systematic researches take into account: 1) the chemical analysis of the crude rubber (the water, resin, ash and nitrogenous substances present together with the acidity); 2) the physical constants: viscosity of the rubber solutions; vulcanisation coefficient; mechanical test of vulcanised rubber; tension test; degree of elasticity; of elongation (permanent deformation etc.).

In the present condition of knowledge on the question, it remains necessary to accept the definition of the producers and dealers; rubber of good

quality is clean, sufficiently dry, sound, well preserved and not very variable. The dealer indeed only reflects the wishes of the manufacturer, and the latter prefers the rubber that suits him best and will pay a higher price for it. He requires that the rubber shall be :

1) Clean and sufficiently dry to reduce loss in washing, which, when considerable, increases the loss in weight of the raw material, necessitates more labour and makes greater demands on the apparatus and the fuel driving the machines ;

2) Sound, because sticky (*i. e.* resinous) rubber contaminates the pure product, vulcanises badly and also entails loss ;

3) In a good state of preservation, for any deterioration means a loss of useful material, and owing to the mode of preparation of crude rubber, it is more or less liable to spoil.

4) As little variable as possible ; this is necessary, because all the treatments to which rubber is subjected in the factory are empiric, and with an invariable rubber the formulae need not be altered.

It is necessary also to mention the preference given by manufacturers to certain rubbers for reasons unknown to dealers or producers, which they are unable to detect.

The author deals with the grounds of this preference in the case of *Hevea brasiliensis* rubber in Brazil, and in the plantations of the Middle-East. Since competition has arisen in the markets of the world, the manufacturer is always willing to pay a higher price for "Para hard core" than for "white crepe first latex" (which are the two best qualities), without taking into consideration the fact that "Para" loses 18 to 20 % in washing and "Plantation" 2 % at the most.

The author is, however, of opinion that this difference in the prices quoted which has prevailed for twenty years, though no doubt it has now decreased, has sufficed to insure that Para rubber is still really superior in quality to "Plantation".

This difference in quality has been attributed to three causes : 1) the origin of the trees ; 2) the age of the trees ; 3) the preparation process to which the raw rubber is subjected. The author draws the following conclusions from his examination of the question.

1) The origin of the trees cannot account for the difference in the American and Asiatic products ;

2) the effect of age upon trees ready for tapping is very slight and quite insufficient to explain the difference observed ;

3) although it is impossible to adduce actual proof, it would appear that the principal cause of the difference in the quality of "Para fina" and "first latex" undoubtedly lies in the method of preparation.

After discussing the alleged defects of the commercial varieties of both "Para" and "Plantation" rubbers, the author expresses his belief that both could be improved. For Brazil the practical lesson to be drawn from this fact is that with sufficient care, "Plantation rubber" could be made as acceptable to the manufacturer as "Para fina".

The author believes that the improvement of Brazilian rubber is to be sought in the reduction of the net cost for : a) eastern competitors can improve their rubber until it is practically equal in quality to "borracha" ; b) since Brazil no longer controls the market, she cannot fix the price of rubber merely by supplying rubber of better quality ; c) only taking into account the exceptional quality of the product would mean reducing the amount exported to a very insufficient quantity. This does not mean that the quality of the rubber should be sacrificed. On the contrary it is necessary : 1) to keep the manufacturing quality equal or superior to that of the eastern rubbers ; 2) to improve the commercial quality by more careful preparation and the suppression of adulteration.

In fact the reduction of the water and of the impurities to 2 % in weight is equivalent to reducing the cost price, since with "borracha" in leaves coagulated by "defumação", it is possible to obtain on the European markets a plus-value of 14 % as compared with the price of the balls. The leaf form has the following advantages over the balls : 1) with equal weight, a plus cash value of 14 % ; 2) freight paid for 2 % of impurities instead of for 20 % ; 3) export dues paid on 2 % of impurities instead of on 20 %.

In short, the author is of opinion, that the difference in the quality of the two *Hevea* rubbers, the Brazilian and the Indo-Malayan, is almost entirely due to differences of preparation ; that it is decreasing, and may disappear altogether. He also believes that, since the manufacturers recognise that the quality of the best Amazonian product is equal or superior to that of "crepe first latex", it is only necessary to maintain this quality. Further that for economic reasons, it would be advisable to improve the commercial quality of "Para fina", as its quality must not be relied upon as the sole means of solving the "borracha" crisis.

G. A. B.

422 - Investigations made in Java Concerning the Origin of the Latex of *Hevea brasiliensis*. — BOBILIOFF, W., in *Archief voor de Rubbercultuur in Nederlandsch-Indië*, Year. 5, No. 3, pp. 95-111, figs. 5. Buitenzorg, March 1921.

Different methods of tapping *Hevea brasiliensis* were carried out with a view to making direct observations as to the exact origin of the latex and to ascertain the direction of the flow and the effect of grafting a species having a yellow latex on another having a white latex.

The results obtained from this investigation may be summarised as follows :—

1) The change of colour of the latex from yellow to white in the neighbourhood of the tapping cut which gives a yellow latex, makes it possible to control the extraction sphere of latex when tapped. The appearance of white-coloured latex at places where previously the yellow colour was present indicates that these places are exhausted and that secondary latex-building is taking place.

2) The flow of latex to the tapping-cut is very slow and about 2½ months is required to cover a distance of about 1 metre.

3) The extraction by ordinary tapping from above downwards occurs only from the latex vessels which lie underneath the cut and about 1 cm. on each side of the cortex.

4) The extraction of latex by tapping from below upwards is slightly less than by the reverse method.

5) If the cut is high above the ground, the latex is extracted also from the roots, but only from the places lying below the cut or in the vicinity. In this case the latex is extracted from the side roots, but only from those under the tapping cut.

6) Above the tapping cut there is no extraction of latex by ordinary tapping.

7) Three year old grafted trees from a common parent with yellow latex grafted on stock with white latex continued to give the yellow latex and the new stock white latex.

423 - **Sugar Beet Cultivation in Louisiana, United States.** — COATES, F. C., and KIDDER, A. F. (Louisiana State University, Baton-Rouge, Louisiana) in *The Journal of Industrial and Engineering Chemistry*, Vol. XIV, No. 3, pp. 213-214, Washington, March 1, 1922 (1).

SUGAR CROPS

A long series of experiments have proved that it is possible to grow sugar beets, of high sucrose content and purity combined with great productivity, in Louisiana and presumably also in the other southern States of the Confederation. The best results are obtained by late spring planting. The yields averaged 18 tons per acre, the weight of the beets was 1.5 to 2.5 lb., the purity about 85 % and the sucrose 14 %. In order to obtain such results it is, however, necessary to use good seed which breeds true to type. Seed grown in the United States to-day fulfils this requirement and appears to be even better than European seed.

The first experiments in sugar-beet growing were made by one of the authors in 1898, at the Louisiana State University, with seed imported from Europe and sown in November; afterwards sowings were made in August, and mature roots obtained in February. Under these conditions beetroots can be matured in May, June and July, and probably also during March and April. The tonnage per acre in Louisiana is probably heavier than elsewhere, and the sucrose and purity are high enough for commercial purposes, while the cost of cultivation is much less than in most beet-growing sections, being from 15 to 20 dollars per acre.

A series of analyses shows that beets after harvesting will keep for a week or more without appreciable loss in sucrose or purity. These results are probably too favourable, but it is reasonably certain that, after harvesting, beets in Louisiana will not deteriorate more in May, June and July than sugar-cane in Cuba during the same months.

Beets planted on January 24 are ready for harvest by May 8 and probably earlier; they can, however, be lifted in good condition until July and even later. If beets could be matured early, they could be worked

(1) It should be noted that in the district in question, the sugar-cane is grown to its climatic limit. (Ed)

into sugar in Louisiana and thus extend the sugar season for 3 months or longer. This would double the value of the sugar factories which normally can only run for about 2 months in the year. G. A. B.

425 - **The Possibility of Growing Tea in Italy.** — CAVARA, F, in *Bollettino dell'Associazione italiana Pro piante medicinali, aromatiche ed altre utili*, Year IV, Nos 7 and 9, pp. 106-109 and 133-138. Milan, 1921

Long experience has already proved that the tea-plant can grow in certain parts of Italy, it has been successfully cultivated in the Botanical Gardens of Pavia (by putting it under cover during the winter), Florence, Pisa and Naples, and also in the Borromean Islands on Lake Maggiore etc.

According to the opinion both of the author and CARNEL, there exist in South Italy, Sardinia, and Sicily very sheltered shady valleys where tea could be cultivated. BECCARI was of opinion that the tea plant would thrive in Italy in the olive zone, where it could, if necessary, be grown beneath the olive-trees or vines, and thus obtain a little shade. It has been proved, however, that the dry maritime climate of the Mediterranean does not suit tea and that this is the reason of the failure of several experiments in growing the plant in Sicily.

Twenty years ago the author distributed as an experiment some young tea plants to several landowners from Tuscany to Calabria. As it was a question of a new crop with special requirements as to temperature and atmospheric and soil moisture (the tea-plant cannot stand lime), it is not surprising that most of the trials failed. In one case however on an estate in the commune of Bagni di San Giuliano (Prov. of Pisa), all the plants struck root and grew, producing after some years both flowers and fruits, and very fragrant beverage was made from the leaves. The author strongly recommends the renewal of these experiments. They could also be made in some suitable parts of Eritrea and Somaliland. F. D.

426 - **Manuring Coffee.** — I Manures for Coffee Plantations, in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No 9, pp 317-319, bibliography, London, 1921 — II, Coffee in Guatemala and Costa-Rica, *Ibidem*, pp 316-347 — III HERMANN, J. A., Cafeicultura e os adubos, in *Annaes da Sociedade Rural Brasileira*, No 17, pp 1043-1050 São Paulo, November 1921 (1)

The effects of the application of chemical manures to Coffee plants have not been studied for a sufficiently long period to justify their recommendation for general use.

Such active artificial manures as sulphate of ammonia, sulphate of potash, nitrate of soda, superphosphate etc., are undoubtedly of value for annual crops where immediate results are desirable and the temporary character of the fertiliser is of secondary consideration, but for coffee or any other perennial plant where a slower and more lasting effect is required a similar value has not been established. In fact Sir John LAWES has

(1) See *R* Jan 1915, No 18 (Ed)

stated that "most decidedly the active artificial manures would not be suitable for the coffee-tree", but considerable difference of opinion on the point seems to prevail in all coffee-growing countries.

The manures, however, that can be safely recommended are those of an organic character, including prunings, leaves, weeds, coffee pulp and other refuse obtained in the preparation of the coffee-bean, farm-yard manure, green-manures, bone, dried blood, oil-seed cake, guano and fish manure, to which may be added the organic substances, wood-ashes and lime. The use of farm manures and green manures may not be practical on all plantations, but the suggestion of rotting down straw to take their place deserves consideration. As wet straw alone will not rot down, and some active form of nitrogen is required to start the process, this may be supplied by the urine from stock, or by passing sewage through a filter-bed made of straw (1).

The selection, however, of any of the manures mentioned can only be decided as a result of knowledge of local conditions and after experiment, for it must be based on convenience and cost.

A manure of considerable value may be made by mixing coffee-pulp with bone-meal (in the proportion of about 1 part of bone-meal and 20 parts of coffee-pulp), together with any general refuse from the plantation, heaped or buried for several months in a place where there is protection from sun and rain. When sufficiently decomposed the manure may be dug in round the trees, without injury to the roots if possible, or laid on as a mulch. The pulp together with the parchment and other refuse from the factory is valuable on account of the nitrogen, phosphoric acid, potash and lime it contains, while the bone-meal is useful as supplying phosphoric acid, lime and nitrogen. The percentages in the coffee-pulp of these constituents are considerably higher in material when fresh than after exposure for several months to sun and rain, and it is important to preserve it as above described. Any wood-ashes that may be available from burning rubbish on the plantation can be put into the manure heap to increase the supply of potash. As tropical soils are often deficient in lime, slaked lime can when necessary be distributed over the whole plantation before applying the mixed or other manures, at the rate of about 15 cwt. per acre, or with trees 3 ft × 3 ft, this would be approximately 3 lb. per tree.

TABLE I. — *The annual requirements for 1000 Coffee Plants (at different ages) of nitrogen, potash, and phosphoric acid.*

Age of tree	Nitrogen	Potash	Phosphoric acid
	lb.	lb.	lb.
First 4 years . . . . .	9.87	23.62	2.49
From 5 to 8 years . . . . .	35.7	76.92	19.57
From 9 to 20 years . . . . .	28.87	45.83	15.76
After 20 years (old trees) . . . . .	5.09	30.53	9.48

(1) See R. March 1922, No. 236. (Ed.)

II. — As regards the manuring of coffee-trees in Guatemala and Costa Rica, it is stated that coffee has been grown in these countries for nearly a century upon soil characterised by its high humus content, for the plantations occupy the site of original forests and much leaf-mould is produced by the plants and the shade trees. There is, however, a clear need of manure, for the soil is usually deep and sometimes stony. Lime and natural manures are recommended in preference to artificial manures.

III. — The author of the 3rd publication states that a large number of the old coffee plantations in the State of São Paulo of Brazil show signs of degeneration owing to neglect for several decades and especially to insufficient supplies of humus and lack of regular manuring. The author estimates that a crop of 750 kg. net of coffee has been obtained per 1000 trees during the last 10 years from the 800 million trees in bearing. The amount of nutritive substances removed from the soil is given in Table II. In order to replace these elements, it would be necessary to apply the natural or artificial manures given in Table III, but these quantities would have to be doubled or trebled in order to restore the plantations to their original condition.

TABLE II. — *Exportation of coffee from the State of São Paulo from 1850-1919 with the amount % of fertilisers extracted annually.*

Coffee Exports		Fertilisers extracted annually					
in the 10 year periods	Annual average in thousands of bags	Nitrogen	Total ash	in the ash			
		1.75 %	2.84 %	Phosphoric acid 12.53 %	Potash 68.25 %	Lime 6.15 %	Magnesium 11.11 %
		tons	tons	tons	tons	tons	tons
1850-59. . . . .	2 500	2 625.0	4 260.0	578.9	2 779.7	260.7	468.6
1860-69. . . . .	2 835	2 976.8	4 830.8	605.3	3 152.1	295.7	531.3
1870-79. . . . .	3 675	3 858.8	6 262.2	784.7	4 086.1	383.3	686.9
1880-89. . . . .	5 473	5 746.7	9 326.0	1 168.6	6 085.2	570.8	1 025.9
1890-99. . . . .	7 226	7 587.3	12 313.1	1 542.8	8 034.3	753.6	1 354.2

1910-19. . . . .	9 821	10 312.1	16 735.0	2 101.7	10 921.0	1 021.4	1 837.5
Average per bag . . . . . kg.		1.050	1.704	0.214	1.114	0.104	0.187

In order to find out whether it would pay to improve old coffee plantations the author carried out experiments, in 1913, on a 60 to 70 year old plantation belonging to the " Instituto Agronomico do Estado de São Paulo (Campinas) on 6 series of plots: A) control plots, without manure, but ploughed and pruned; B) 28 kg. of farmyard manure per tree; treated otherwise like A; C) 17 kg. fresh coffee pulp per tree; treated otherwise like A; D) 0.56 kg. superphosphate + 0.2 kg. potassium chloride + 0.2 kg. ammonium sulphate per tree; treatment otherwise as for A; E) 7 kg. farmyard manure + 0.15 kg. basic slag + 0.075 sulphate of potash +

0.065 kg. of nitrate of soda per tree, treatment otherwise as for A. The manures were applied 3 times, viz., in 1913-1914, in 1914-1915 and in 1916-1917. Table IV gives the results obtained after 8 years of experiment-

TABLE III. — *Quantities of Manures necessary to replace the substances removed from the soil.*

Ten year Periods	Farmyard manure annual average	Chemical fertilisers		
		Chloride of potassium containing 50 % potash	Nitrate of sodium containing 16 % nitrogen	Basic slag containing 16 % phosphoric acid soluble in citric acid

The author estimates that the minimum return a good cultivator should obtain from a coffee plantation is 28.17 %, the amount produced by the plots of series E. G. A. B.

427 — **The Cocoa Industry of Ecuador and Possibilities of Introducing certain Varieties into Other Countries.** — TUDHOPE W. E. D. (Director of Agriculture, Gold Coast) in *Bulletin of the Imperial Institute* Vol. XIX No. 3, pp. 318-360. London, 1921

Report of investigations made chiefly in connection with the "Arriba" cocoa which constitutes over 50 % of the total export of cocoa from Ecuador.

The variety grown is almost exclusively that known as "Cacao Nacional" which possesses large pods weighing as much as 3 ¼ lb. and containing a large quantity of well formed beans; the seed contents of a number of pods examined, ranged from 40 to 51 (average per pod 44). This is evidently a superior type and produces on an average, 1 lb. of cocoa per 7 pods.

In the "Arriba" Province some fruits ripen every month of the year, though there are only 3 recognised crop seasons viz. February to June, July to October, and November to January.

During recent years Venezuelan varieties have been planted to a certain extent, as they have the reputation of giving a heavier yield and of maturing earlier than the former type, but apparently the Monilia disease has proved more virulent with these newly tested varieties, and apart from the fact that the trees do not grow so tall and big as the Cacao Nacional and therefore overcrowding is avoided, the superiority question is still open.

Practically all the cocoa exported is merely dried in the sun, a process which under ordinary conditions only requires 7 days.

The author considers that if the beans are given only a slight fermentation in mass before drying, more satisfactory results might be expected. Apparently in Ecuador only a very light fermentation is necessary to produce the desirable "chocolate break" in the dried bean. It may be con-

cluded that the beans are of superior quality to those for example of the Gold Coast, where it is reported that 6 days fermentation in boxes is necessary before even sun-drying is employed, in order to produce a similar chocolate break in the bean. The cocoa bean with the lightest coloured testa possible has the highest commercial value but it does not follow that this is "unfermented cocoa" in the Ecuador types. If drying is unduly prolonged by dull weather, a condition similar to over-fermentation is brought about resulting in discoloration of the testa in the form of little brown or black spots, a condition often present if the pods are over ripe before they are gathered, or if they are left in heaps some time before drying, despite suitable weather conditions for sun-drying.

On an average twenty labourers with 15 mules are regarded as sufficient for the maintenance of a plantation of 100 000 bearing trees. A labourer is paid about 1 *sucre* (= 2s 6d) per diem.

For valuation purposes the value of a plantation has been estimated by local banks at an average of about 80 *centavos* (2s) per tree in bearing.

The price of cocoa in 1920 was 42.50 *sucre*s per quintal in Guayaquil but there is obviously a wide margin for fluctuation which serves to indicate the profitable nature of the industry. The total costs to port of shipment are reported as about 8 *sucre*s per quintal (20s per 100 lb); the cocoa is shipped in bags containing 175 lb. net.

The "Asociación de Agricultores del Ecuador" which comprises all the producers and possibly also all the exporters of cocoa has for its main object the defence of the industry against the speculations of foreigners which tend unduly to lower the price of the local product, and is empowered to collect an export tax, in addition to the official Government export taxes.

This investigation was made with a view to the possibility of introducing the "Nacional" variety into the Gold Coast, Ceylon and other countries, and comparisons are made between the systems adopted on the Gold Coast and those employed in Ecuador.

M. L. V.

428 - **Factors other than those of Environment influencing the Alkaloid Content and the Yield of Latex from the Opium Poppy in India.** — ANNETT, H. E. (Agricultural Chemist to the Government of Bengal), SEN H. D., and SINGH H. D., in *Memoirs of the Department of Agriculture in India*, vol VI, No. 1, 60 pp., figs 20, 1 diagr. Calcutta, Sept 1921

The authors have identified numerous subsidiary factors which influence the quantity of morphine contained in opium; their influence will be treated in a series of works beginning with the present. A summary is made of the works of different authors on the subject of the factors which influence the quantity of active principles produced by other plants and these results, taken in conjunction with those which they have themselves obtained, throw much light on the subject of the functions of alkaloids among plants.

Tables show the plot yield of opium at each successive incision and the content in morphine as well as the opium yield for 1000 capsules,

and from the experiments made in 1917-1919 to decide the question whether the quantity of morphine contained in the opium from the second and subsequent incisions can be modified by varying the intervals of time between the successive incisions, the authors draw the following conclusions:

The opium of the 1<sup>st</sup> incision is richer in morphine than that of the subsequent incisions; in practice, the method to adopt would be to collect the latex given off in the first few seconds from the surface of the capsules after the first incision. Possibly, if this first exudation of latex were removed immediately, a more copious flow of latex per capsule would be obtained in the 2<sup>nd</sup> yield made the following morning and in the succeeding yields, because the coagulation of the first deposit of latex around the surface of the incision must obstruct its free flow.

**INFLUENCE OF VARIATIONS IN THE METHOD AND PERIOD OF THE INCISION ON THE COMPOSITION OF THE OPIUM** — The method of incision varies in the different opium-producing countries; the authors describe the methods adopted in India, France, Germany, Egypt, Asia Minor, Persia, China and Australia. They compared, by experiments made on a large scale, the Turkish mode of spiral incision, the transversal, vertical, etc. From tables showing the results thus obtained and a diagram illustrating the yield in opium according to the number of blades of the lancet used in making the incisions, etc., the authors draw the following conclusions.

1) The Turkish mode of spiral incision does not give a greater yield of opium than the Hindoo vertical incision, which is much simpler. The same holds good with regard to transversal incisions.

2) There is generally no advantage in making more than one vertical scarification at each incision.

The yield of latex is not increased in proportion to the number of scarifications; if 5 or 6 vertical scarifications are made, the yield is even less than with one only. Generally, 3 scarifications per incision yield much more than is obtained by one at the 1<sup>st</sup> incision; but in subsequent incisions, the yield obtained by the first method diminishes to such an extent that the final total yield is lower with a number of scarifications than with one only.

3) If at each incision instead of making the scarification along the whole length of the capsule, it be limited to  $\frac{1}{3}$  or even less, the yield of latex is considerably less at the 1<sup>st</sup> incision. But the dry matter of this latex contains a higher percentage of morphine; further, in subsequent incisions, this percentage diminishes less rapidly.

4) An experiment for the purpose of testing the effect of the number of lancet blades used in making the incision shows that the 6-bladed lancet gives a total yield in opium per capsule higher than one with 2 or 4 blades, even to the extent of doubling it.

5) There is no difference either in the opium yield or morphine content according to whether an incision be made in the morning or in the afternoon.

6) The authors call attention to the fact that the size of the capsule and vigour of the plant have a great influence on results. It seems that a

large capsule on a vigorous plant may receive more than one scarification at each incision without suffering to any extent whereas a weaker capsule may give no latex at all if more than one scarification be made at each incision.

M. L. Y.

429 - **Influence of Solar Radiation on the Culture of Belladonna and on the Formation of Alkaloids in the Leaves.** — GORIS, A., and DELMARD, A., in *Comptes rendus de l'Académie des Sciences*, Vol. 174, No. 3, pp. 183-190 Paris, January 17, 1922.

After cultivating the belladonna: 1) in the sun; 2) 6 weeks in the shade and then 6 weeks in the sun; 3) in the shade; and after gathering the leaves on the appearance of the first 2 or 3 flowers, the authors have observed that the leaves of group 1, at the 1st gathering, contained 0.65% (taking the weight of the dry leaves) of alkaloids, and on the 2nd gathering, 0.52%; the leaves of group 3 only contained on an average 0.30%. Further the adult plants grown in the sun yielded 3 crops from May to September, whereas the plants of the 2nd group required 3 months before yielding a crop. Finally, the plants grown in the sun yielded an average of 15 gm. of dry leaves each, those grown in the shade, 9 gm. only. Speaking generally the plants grown in the sun, as compared with those grown in the shade yielded 3 to 4 times as many leaves and 7 to 8 times the quantity of alkaloids.

F. D.

430 - **Interplanting of Trees on Coconut Estates. Observations made in Portuguese India.** — FURTADO, C. N., in *The Planter's Chronicle*, vol. XVI No. 13, pp. 219-222 Coimbatore 1921.

The author as a result of observations made at Goa, has found it possible to catalogue the trees which may be allowed to grow on coconut estates with obviously advantageous results.

It should be noted at the outset that coconuts in Goa are usually grown on lateritic or sandy alluvial soils, which retain very little humus; the sub-soil is inclined to be compact and to contain a detrimental excess of moisture. Consequently a careful selection of trees for interplanting, employing deeper rooted varieties than coconut, thus rendering the sub-soil less compact, and varieties which from the point of view of foliage will serve as a useful source of humus, is of undoubted benefit to the plantation in general.

**LIST OF TREES RECOMMENDED** — "Banyan" (*Ficus indica* Roxb.), "Indian coral" (*Erythrina indica* Lamk.), "hogplum" (*Spondias mangifera*), "horse radish tree" (*Moringa pterygosperma* Gaertn.), "belembi" (*Averrhoa Bilimbi* L.), "mango" (*Mangifera indica* L.), "pomelo" (*Citrus decumana*), guava (*Psidium Guyana* L.), "malay apple" (*Eugenia mallaccensis* L.), "box" (*Ficus glomerata*). The last mentioned is chiefly grown along the borders of drains, tanks etc.

In addition to this list, the following, is also given of the trees considered undesirable:—

Portia tree (*Thespesia populnea* Correa), tamarind (*Tamarindus indica* Linn.), teak (*Tectona grandis*), red silk cotton tree (*Bombax Mala-*

*baricum* D. C.), "cashew" (*Anacardium occidentale* L.). "poon" (*Sterculia foetida* L.), "jajube" (*Zizyphus Jujuba* Lamk.), and *Mimusops Kinki* L.  
M. L. Y.

431 - **The Cultivation and Commercial Possibilities of Safflower Seed (*Carthamus tinctorius* L.) in India.** — HOWARD, A (Imperial Economic Botanist) and REMINGTON G S (Consulting Chemist, Aynsme Technical Laboratories, Grange-over-Sands, Lancashire): in *Agricultural Research Institute, Pusa, Bulletin* No 124, pp 1-14. Calcutta 1921 — and *The Chamber of Commerce Journal*, Vol XI,III, No 418, p 81. London, Feb 3, 1922

The safflower (*Carthamus tinctorius*) is widely cultivated in India both as an oil seed and to a much less extent for the reddish dye in the flowers (carthamin). Open sandy and rather dry soils best suit this crop, which is generally sown mixed with grain, barley or wheat.

Various species have been isolated and studied at Pusa, and the author gives a classification of 24 types with notes concerning their general habit, leaves, bracts and flowers, and the percentage oil content of each type respectively

A number of seed samples have recently been analysed at Poona by MANN and KANTIKAR with the following average result. — husk 50.8%; kernel 49.2%; oil in the whole seed (average of 55 samples) 31.6%; maximum 36.9%, minimum 25.4%. The various constants of safflower oil were determined and particular attention paid to its characters after heating under well defined conditions. Apparently it is only at 300° C in oxygen that the well known characteristic results of heating the oil become evident. By heating to 186° C in oxygen, a very marked reduction in the length of time required for drying was obtained.

Testing investigations were made in Great Britain under the direction of the author REMINGTON into the commercial possibilities of safflower. Reference has already been made to this work in the Scientific Reports of the Agricultural Research Institute, Pusa 1920-21 (1), but the author here gives full details of the various tests carried out.

The economic uses of this oil have already been summarised (1) and it is also stated that it can be utilised with success as a substitute for oil in paints and varnishes.

In India, the meal should be used to best advantage in the manufacture of soaps, or as a slow acting manure for agricultural purposes. An analysis of the meal was made with the following results: % moisture 7.50, oil 2.21, albuminoids 15.96, carbohydrates 35.48, crude fibre 32.88, mineral ash 5.97. As feeding material however the meal should be considered useless on account of the high crude fibre content.

Although the investigations so far undertaken have proved undoubtedly the high economic value of the safflower, further investigations are in progress in the Pusa laboratories as to the protein value of the seed, etc.

432 - **The Cultivation of Capsicums in Algeria.** — GIBIER L., (Conseiller agricole à Orléansville) and FOURNIER F. (Chef de la Station expérimentale de Ferme-Blanche (Oran), in *Revue Agricole de l'Afrique du Nord*, Year 20. No. 131, pp. 76-78, figs. 2. No. 132, pp. 96-98. No. 133, pp. 109-110. Algiers, Feb. 1922.

HORTICULTURE

During the last three years, distinct progress has been made in Algeria with regard to the production of capsicums, especially in the Perrégaux region, which possesses a sandy loam particularly adaptable to their cultivation. The area covered from 1919-21 is given as 130 hectares.

The recent establishment of several factories, specially constructed for the manufacture of red pepper, pickles etc. has done much to emphasise the industrial value of capsicums and the authors state that should the drying processes and the methods of cultivation in general, be perfected, there is every possibility of obtaining a condiment of first-class quality which should rank with the best produced in Spain which is recognised as the leading country for red pepper.

The actual varieties cultivated are not clearly defined, but the following classification has been found possible.

The Dwarf Red Tomato var., almost spherical in shape; scarlet; pungent taste. This is the chief variety grown (80 ha). Three crops per year are obtained in June, end of September and in November or December; used for red pepper.

2) Improved Bull-nose or Sweet Mountain var., large fruits, blunt, with squared ends; furrowed; thick flesh, mild flavour. Used for pickles or eaten fresh.

3) Long Red Spanish pepper: flavour strong, cultivated in Orléansville.

4) Cayenne pepper, small; red; shape slightly curved; strong and burning flavour. Chiefly used by natives, but not often for commercial purposes.

The best results have been obtained on light soils, rich in humus, especially on the sandy loams in Perrégaux. Ploughing takes place twice, in December and in early March, and directly after the second ploughing, ridges are made 40 to 70 cm. apart. Farmyard manure is applied at the rate of 10 000 to 25 000 kg. per hectare; the addition of leaf mould has in some cases been found advantageous.

Sowings are made in December or January, and the seedlings are ready for transplanting towards the end of March or in early April, and are planted about 30 cm. apart in some cases and more thickly in others (20 to 25 cm.). Of the two methods employed viz. 1) flooding the furrows previous to transplanting and 2) leaving the furrows without water until later, the first has proved the more satisfactory.

During the growing period, frequent waterings are given in the early stages and afterwards at intervals of 15 to 20 days up till the fruiting stage; from which time onwards, until cropped, only 5 to 10 days is considered necessary.

The cultural operations are limited to two or three hoeings.

The harvest season starts towards the end of June and continues

until the beginning of January, but the later ripening fruits are of inferior quality.

A description is given of the drying process employed for the capsicums intended for red pepper manufacture and also for pickles etc. In the first case, the waste product is estimated at 6 to 7 % of the total weight of dried capsicums. In the second case usually about 50 days are allowed before the preserves are taken out of the hermetically sealed recipients, which are then bottled for sale. The prices obtained in Algeria are subject to considerable fluctuations, but the following average for three years is given: dried capsicums, 300 to 400 frs. per quintal; fresh capsicums: 25 to 70 frs. per q.

As regards cost of production and net profit per hectare, an estimate is given for the Perrégaux district in 1921 (in francs): land rent 70; soil preparation 70; ridging 20; manuring (20 qx at 5 frs. per q.) 100; transport of manure etc. 50; collection of plants and transplanting 70; hoeing and weeding 300 (15 to 18 frs. per person per day); thinning out fruits, 30; irrigation, 60; manual labour for about 20 waterings, 150; cropping (collecting of 200 qx of capsicums at 2 frs per q.) 400; general costs 150. Total 1470 frs.

The average yield per hectare is estimated at 200 qx. of fresh capsicums and the total value should be 5000 frs., taking the average sale price at 25 frs per q. The net profit should be therefore 3430 frs. per hectare.

In Orléansville, the net profit, however, is lower, not exceeding 800 frs per ha. and the industry appears to be gradually dying out in this district.

M. L. Y.

433 - Possibilities of the Mushroom Industry in India. Bosc S R (Professor of Botany, Carmichael Medical College, Calcutta), in *Agricultural Journal of India*, vol XVI, No 6, pp 613-617 Calcutta, Nov 1921

Up to the present time there has been no regular cultivation of edible mushrooms in India, but as a result of the author's investigation as to the nutritive value of the indigenous wild varieties it appears highly probable that mushroom growing will become a special industry in India.

A chemical analysis has been made of the most common edible varieties found in Bengal and it is to be noted that some of them are superior to the English mushrooms etc. as is shown in the following Table.

Species	Protein	Carbo- hydrates	Fats (Ether extracts)	Ash	Moisture
					analysed in dry con- dition
<i>Volvaria terastius</i> . . . . .	2.28	trace	0.18	—	—
<i>Collybia (Leptota) albuminosa</i> . .	12.8	14.8	trace	—	—
<i>Agaricus campestris</i> . . . . .	2.1	1.60	0.37	0.15	95.2 %
Puff balls ( <i>Gasteromycetes</i> from Bankusa) . . . . .	2.20	1.35	0.56	0.16	93.85
English edible. . . . .	0.18	0.46	0.03	—	—
American Edible. . . . .	2.25	4.95	0.20	—	91.30

The tissue culture method in sterilised dung medium has been adopted to obtain artificial cultures of these local Agarics. The object is to make native spawn and thus facilitate production on a large scale and consequent economic development.

The results of an enquiry instituted by the Royal Botanic Gardens, Kew, prove that there is a ready market for edible mushrooms in Burma, Punjab, Kashmir and Afghanistan, provided that a regular supply is forthcoming.

M. L. V.

FRUIT  
GROWING

434 - **The Avocados of Guatemala.** — LEITCH, MARIE and LEITCH, MARQUERITE, in *Revista de Agricultura de Puerto Rico*, Vol. VII, No. 4, pp. 5-35, figs. 10, San Juan, October, 1921.

The Guatemala varieties of Avocados (*Persea gratissima*) differ from those of Porto Rico origin in various ways: 1) The former have a thick rind and adherent stone, which enables them to be exported, while the native varieties have a thin skin and the stone moves about in the cavity, so that the interior of the fruit is injured during transport.

2) Many of the Guatemala varieties grow as high as mango-trees, and are therefore able to bear more fruit than the native varieties.

3) Some Guatemala varieties fruit at different seasons, spring, summer, autumn or winter; thus, ripe avocados can be obtained throughout the year.

4) The Guatemala varieties are much richer in fatty substances than the native kinds. According to the variety, the former contain 16 to 30 % of fatty substances (1) and the latter only 10 %.

5) The Central American varieties fruit much earlier; the "Lyon" variety is mentioned as bearing fruit in the nursery, and is said to produce a crop from the age of 4 years. The "Puebla" variety begins to bear when 2 years of age, like "Puerta" which, when it is 4 years old, produces 100-300 fruits per tree while the "Spinks" variety fruits 3 years after being grafted.

6) A large number of Guatemala varieties bear fruit at high altitudes in their native country at from 900 to 1200 and even 1500 metres above sea-level. The Porto-Rico varieties, on the other hand, are sterile at high altitudes. Thus, the deforested hills of Porto Rico could be covered with woods of "aguacates", and a profitable crop might be obtained.

7) The Guatemala varieties are usually resistant to strong winds.

8) Some of these varieties produce good wood and dense shade, which makes them useful in the Guatemala coffee plantations. Two crops can thus be obtained on the same ground. These trees can bear a great number of fruits without damage to their branches.

6) The fruit of several of these varieties can be left hanging on the tree for some months.

Of the 30 varieties of Guatemala avocados, that have been imported

(1) See *R. Sept.* 1920, No. 8:28. (Ed.)

into Porto Rico (Plantación de Mangos y Aguacates de Bayamón), 5 are specially recommended for growing for the market; these are: *Fuerte*, *Spinks*, *Dickinson*, *Sharpless* and *Puebla*. Their characters are as follows: *Fuerte*: fruits from January to August. Weight of fruit 325 to 400 gm. contains 30.72 % of fatty substances.

*Spinks*: fruits from April to August; weight of fruit 450 to 560 gm. contains 21.75 % of fatty substances.

*Dickinson*: fruits from June to October: weight of fruit 330 gm. contains 20.36 % of fatty substances

*Sharpless*: fruits from October to February; weight of fruit 560 gm. contains 24.23 % fatty substances

*Puebla*: fruits from December to February; weight of fruit 225 to 280 gm.; contains 26.68 % fatty substances

Among the other varieties may be mentioned: *Lyon*, *Dickey A.*, *Perfecto*, *Atlisco*, *Mérito*, *Grande*, *Taft* and *Blakeman*

The same variety cannot be obtained from seed and hence grafting is necessary. As *Persea gratissima* grows into a large tree, it should be planted at intervals of 9 or even 12 metres, if the soil is very fertile. The same precautions must be taken as in planting a fruit-tree in the orchard: the hole should be 60 cm deep and 1 m wide, the soil must be mixed; with well decomposed dung and compost, and then filled up to form a mound 30 cm in height, and 1.50 m in diameter, etc. When once planted, the young tree must be protected from the wind and sun by means of canvas, or palm leaves; this shelter is no longer necessary after it has taken root and a new bud has developed. It must, however, be protected against the wind for at least a year.

It is advisable to place dry grass round the tree and this should be changed every 3 months. A prop is indispensable, for the tree must grow perfectly straight. It should be watered in dry weather.

The analysis of the edible pulp of the "aguacate" gives the following results (1): Water 72.8 %, protein 2.2 %, fatty substances 17.3 %; carbohydrates 3.4 %, crude fibre 1.9 %, ash 1.4 %. The avocado is thus a fruit of considerable food value and is eaten in large quantities by the working classes of Guatemala.

The cultivation of *Persea gratissima* in Porto Rico is likely to develop considerably, not only on account of the actual value of the fruit, but because of the possibility of exporting it to the United States. Porto Rico is the only tropical possession of the United States which is near enough to satisfy the demand for avocados, as both the Philippines and Hawaii are too far off.

P. C.

435 - **Propagation of Date Palms by Seed.** - TRABUT, in *Comptes rendus de l'Académie d'Agriculture de France*, Vol VII, No 33, p 718-721. Paris, October 1921

The date-palm is generally propagated by cuttings taken in the spring. These cuttings, however, do not always strike, and are in any case, very

(1) See *R. Sept* 1920, No 828 (*Id*)

liable to be infested by parasites, especially by the scale-insect, *Phoenicococcus marlatti*, which attacks the cuttings before they are planted out.

On the other hand, date-palms are easily propagated from seed, but in this case, the characters of the variety, especially when it is a good one, are not reproduced in their entirety. Date palms are dioecious, and when fertilised artificially, the offspring is directly influenced by the parents. The natives, however, never take into consideration the origin of the pollen. For some years past, male palms with all the characters of the "deglet nour" variety (which is much in request for export), have been observed in the American Experiment Stations.

The female date-palms fertilised with the pollen of these valuable male trees have produced offspring similar, except for some slight variations, to their parents. The author has received some "deglet nour" pollen from America and used it at Biskra for fertilising bunches of the same variety. The dates thus obtained are very fine and have a smaller stone than the fruit of bunches fertilised with the pollen used in the district.

Thus date-palms bearing choice fruit can now be obtained from seed, which is very economical, for a date-palm raised from seed bears fruit sooner than one grown from a cutting, and it also makes a more vigorous tree.

VINE GROWING

I. — "Luglienga" is a white grape peculiar to Piedmont where it is cultivated even in the valleys of the Alps.

It is also known in Lombardy and even better in Venezia, where it is grown under the name of "San Giacomo".

The vine is distinguished by its early ripening and has to be trained on trellises.

Luglienga must be pruned for long canes, but if the stock is prolific, bunches of fruit are seen on the shoots of the spurs and also on the shoots of the vertical portion of the fruit stock, shewing that the lower buds are fertile. The author mentions the case of a vine-grower who trained "Luglienga" at Milazzo (Sicily) on horizontal cordons, and made an annular incision in the fruit buds of the spurs; he gathers the grapes at the beginning of July, before the Algerian and Tunisian grapes are ripe.

Manuring with potassic salts (to increase the sugar content and diminish the acidity), was more successful than annular incisions in securing early ripening.

The cultivation of this table grape, which for one month has no rival on the market, is most profitable, and the author advises its extension.

Average weight of ripe bunch 192 gm.; must composition: sugar 17.92 %; total acidity 5.70 per 1000; cream of tartar 4.28 per 1000.

II. — PIROVANO states that he detected the Muscat aroma in 2 hybrids I. P. 6 and I. P. 7 fertilised with the pollen of "Ferdinand de Lesseps" which had been obtained in England by PEARSON from a cross between a white Chasselas and Isabelle or strawberry grape. Isabelle has a foxy taste which is much less noticeable in Ferdinand de Lesseps (in which it is transformed into a pleasant flavour) and still more slightly in these hybrids which have a muscat aroma. Special mention should be made of the "hybrid Pirovano 7" (I. P. 7), the result of the cross "Madeleine royale" × "Ferdinand de Lesseps". It is a very early, strong prolific vine, though not without defects. It becomes weakened by grafting on an American stock, or a European × American hybrid, and like all the varieties of *V. Labrusca* and their hybrids, is subject to tillosis. Long-lived and productive vines can however be obtained by a careful choice of the soil, stock and fertiliser.

III. — Prof. SANNINO calls attention to the good qualities of the blue Portuguese vine, which is characterised by the early ripening of the fruit and the fact that its grapes are suitable both for the vat and the table.

PULLIAT has recommended it for cold districts where it can replace early varieties, such as Pinot and Gamay, being quite as early and more productive. The author advises its use for supplying vat grapes for cold districts in place of Dolcetto (1), for it is more vigorous, and perhaps hardier, while its grapes do not drop so easily.

The author gives the ampelographical characters of this vine which produces purplish-black grapes. Even the lower shoots bear fruit, so that it can be pruned short. As the blue Portuguese vine is very strong-growing and productive, the plants must not be placed too close together. As it is subject to anthracnose, it should be allowed to reach a certain height in districts where the spring is wet. The best results are obtained by growing this vine on warm slopes with a good exposure; at Alba, it does well on hills with a very clayey soil. The vintage of September 1921 produced at Alba a must with the following composition: sugar 19.70 %, total acidity expressed as tartaric acid 5.9 per 1000; cream of tartar 4.78 per 1000. It is desirable to add some bisulphite of potassium during fermentation, as by this means a wine of good colour, with red effervescence and greater acidity is obtained.

This vine is much grown in the neighbourhood of Vienna, and at Mons and Schumberg, where it produces an ordinary table wine of good quality. It is grown in Hungary under the name of "Oporto". The wine

(1) See R. 1920, No. 660. (Ed)

made from the produce of vineyards on the plain has an earthy flavour, but when grown upon the slopes of Transylvania these grapes yield a wine with a clean taste. It is alcoholic, full bodied, soft and well coloured, lacking in acidity and tannin. Under the name of "Plant de Porto" this vine has been largely grown in Champagne in the vicinity of Epernay, where it produces a highly-coloured, full bodied wine. It yields fairly early table grapes which are ready for eating in August, though they are then completely ripe, for the pulp is not very acid, and the flavour not is pleasant, if not very sweet.

IV. — PIROVANO mentions two stocks that he has obtained: 1-37, or "Golia" (1), and 2-59, or "Gagliardo"; they are derived respectively from the crosses 15 612 × *Rupestris* du Lot and 15 612 × *Riparia* 420 A. 15 612 was obtained by CASTEL and is a product of the cross *Carignan* × *Riparia*. Both have an excellent grafting affinity and the diameter attained by the stem is equal to that of European vines. They are also resistant to drought but their chief characteristic is extraordinarily vigorous growth.

Golia does best on acid, heavy, poor soils with a lime content not exceeding 40 %. Its luxuriant growth makes this vine unsuitable for rich soils, unless it can be allowed to develop freely; it could be used to make arbours, as it would cover them very quickly.

Gagliardo can bear the same amount of lime and is suited to damp soils where *Riparia* × *Rupestris* would grow well. The latter runs it very close as regards vigour, and has a closer affinity to European vines.

V. — The author calls special attention to the desirability of developing the cultivation of table-grapes, both as a remedy for over-production, and in order to keep up the price of wine (to insure a fair profit) by decreasing its production.

Basing his advice on his personal observations and on those of Prof. V. RACAH (*L'Italia Agricola*, 1921, No. 12, p. 375), he recommends the following vines: Golden Chasselas, which grows admirably in Tuscany — Luglianga — *Précoce de Courtilier* (with Muscat flavour) — Madeleine Royale — *Panse précoce* — Madeleine angevine — *Précoce de Malingre*, all earlier than Chasselas — Colombana, or S. Colombana for districts near the Tyrrhenian Sea (over 30-40 kg. from the coast the grapes lose their beautiful golden colour) — Salamanna or Alexandrian Muscat which corresponds to the Muscat of Calabria, and the Zibibbo of Sicily — Catarratto Cerletti Muscat for Sicily and Apulia.

VI. — The following information has been taken from a report presented by Filippo ZERLIOLI, a great exporter of Italian grapes, to the "Commissione vinicola" at the Ministry of Agriculture.

MILAZZO. — *Chasselas* (bunch regular, skin thin, berries large; gathered middle of July; yield in 1921, 2000 quintals; vineyard reconstituted on American stocks; countries of consumption: Switzerland,

1) See R. Nov. 1921, No. 1127 (Ed.)

Germany — *Varesana* (bunch regular, berries large, fleshy, hard skins, resistant) vintage, early in August.

BARI. — *Chasselas* vintage early in August; yield in 1921, 1000 quintals, zone infected with phylloxera, vineyard in course of reconstruction; country of consumption: Germany, especially Saxony. Before the War another grape, the black "Tarantino" vat grape, was also sent to Saxony as a table fruit; during the War exportation was suspended and has not been resumed on account of the high cost of production.

LECCE. — *Varesana*, *Somarello*, *uva Rosa* (bunch regular, large berries, fleshy, hard skin, resistant); gathered early in September; yield in 1913, 40 000 quintals, in 1921, 15 000 quintals. Same observations as in the case of Bari.

NAPLES. — *Catalanesea* (bunch irregular, grapes large, yellow, fleshy, skin hard); vintage late; places of consumption: Naples, and in some years, to a small extent, Milan. An attempt has been made to send these grapes abroad, but the consignments had to be discontinued as the fruit does not bear transport.

TERRACINA. — *Muscat* (yellow, scented grape, bunch irregular, skin hard, berry medium size, vintage from middle of August to early in September, production in 1913, 35 000 quintals, in 1921, 45 000 quintals, vines immune to phylloxera. In 1897, an attempt was made to export these grapes, but they were found to travel badly, and at the same time their flavour is not appreciated in Germany.

TERAMO AND CHIETI. — *Trebbiana* (bunch irregular, berry average, colour golden yellow): gathered the first 10 days of September; yield in 1913, 45 000 quintals, in 1921, 45 000 quintals. — *Mondovico* (large, compact bunch); vintage end of September; yield in 1913, 8 000 quintals, in 1921, 8 000 quintals: sent to Switzerland, Germany and some Italian towns, especially Milan. Before the War, "Montepulciano" (a red vat grape), was also sent but the consignments have ceased owing to the high cost of production.

SAN SEVERO. — *Trebbiana* (compact bunch, small yellow grape), vintage middle of September: markets Switzerland and Germany. It has not been exported since 1913, owing to its high price.

BOLOGNA. — *Chasselas* (bunch compact, skin thin, grapes rather large); vintage in middle of August; yield in 1913, 30 000 quintals; in 1921 10 000 quintals; grows in phylloxera infected zone, vineyard under reconstruction: sent to Switzerland and Germany. Before the War, "Negretto" (a red vat grape), was also exported as a table grape. — "Regida" (large yellow berries); gathered early in September.

PISA. — "Bordò," or *Golden Chasselas* (type Bolonais *Chasselas*); vintage early in September; yield in 1913, 7000 quintals, in 1921, 7000 quintals; vineyards already invaded by phylloxera and completely reconstituted; sent to Switzerland and Germany. — *Colombana* (regular, loose bunch, thin skin, average-sized coloured berry); vintage early in September; yield in 1913, 15 000 quintals; in 1921, 15 000 quintals; markets: Switzerland, Germany, Genoa and Milan.

**PLAISANCE.** — *Bianchetta* (bunch regular, skin thin, berry average); vintage in middle of August; yield in 1913, 5000 quintals, in 1921, 5000 quintals; markets, Switzerland, Milan, Genoa. — *Verdea* (bunch regular, skin thin, berry average-sized, resistant); vintage middle of September; yield in 1913, 32 000 quintals; in 1921, 10 quintals; phylloxera-infested zone; vineyard being reconstituted; markets: Switzerland, Germany, Genoa and Milan. These grapes are kept in a room on screens and sent to the markets of Genoa and Milan until April. — *Bazzegano*, or *Besgano* (red table-grape, bunch regular, berry large, fleshy, skin hard); vintage in the middle of September; yield in 1913, 4 000 quintals, in 1921, 4 000 quintals; markets: Switzerland, Germany, Genoa and Milan.

**ALBA** (Piedmont). — *Angela* (large berries, thin skin); vintage late; yield in 1921, 5 000 quintals; markets: Genoa, Turin and Milan. This grape is kept on screens all the winter.

VII. — The annual exports of table-grapes from Italy to Switzerland from 1914 to 1921 were (in quintals) — 23 566 — 14 210 — 19 633 — 13 572 — 83 447 — 22 769 — 29 491 — 61 261; while from France, from 1919 to 1921, they were; 5 797 — 31 993 — 15 382. In 1913, Italy sent 74 000 quintals of grapes to Switzerland, and 387 000 quintals to Germany.

F. D.

438 — **Substituting Shield Grafting for Double Cleft Grafting in Vines.** — FERRICELLI, E. (Consorzio viticolo Trani), in *Giornale vinicolo italiano*, Year 48, No. 8, pp. 72-74 Casale Monferrato, February 19, 1922

Shield-grafting, for some years declared by the best known authorities on vine-growing to be the type of grafting least suited for the re-establishment of vineyards, is now coming increasingly into favour, on account of the good results obtained by many Sicilian vine-growers. The author especially recommends it in its whistle and ring forms, but he does not approve of shield budding or bud-grafting as this form is not sufficiently firm.

The English or double cleft graft unites firmly and the scion grows well for a certain number of years; it does not, however, guarantee long life for the stock owing to the frequent hypertrophy of the tissues at the point of union and the difference in the diameter of the scion and stock which is thereby induced.

Ring grafting affects only the zone of tissues which readily makes second growth (phloem parenchyma and cambium), whereas in double cleft grafting, the incision nearly always severs the supporting tissues from the wood-vessels which cannot be directly united.

The "quatre-lames" generally used is not suitable for making a whistle-graft; and a "tenailles Ottavi" is to be preferred for the purpose. In this implement there are two short-cutting, semi-circular blades fixed at the right distance, which clasp, by means of a strong spring, the branch to be grafted. Thus the instrument cannot swerve from the plane of the cut and if a simple, rotary movement of rotation is given to the pincers, 2 perfectly circular cuts are made on the branch and when these are

completed by the longitudinal cut, the ring of the cortex with its bud can be easily detached.

F. D.

# FORESTRY

439 - **Forestry in Norway and the Official Efforts for its Advancement.** — BJANES, O. T. (Director of Agriculture, Department of Agriculture), in *A Short Review of Agriculture and Forestry in Norway and of Official Efforts for their Advancement* (issued by the Department of Agriculture), 64 pp., figs. 9. Christiania, 1921.

Forest lands cover a considerable portion of the area of Norway, namely over 7 million hectares. The principal forest trees are: Spruce fir (*Picea excelsa*), Scots pine (*Pinus sylvestris*), birch lowland birch *Betula verrucosa* in the low-lying districts and mountain birch *Betula odorata* in the highland districts; *B. nana* covers large tracts of land in the high mountains. In addition to these three types of tree there are also to be found the following: ash (*Fraxinus excelsior*), oak (*Quercus pedunculata* or *sessiliflora*), beech (*Fagus sylvatica*), lime (*Tilia parvifolia*), alder (*Alnus glutinosa* and *incana*), aspen (*Populus tremula*) and several other species.

Considering the northerly situation of the country, the forests extend to a great height above sea-level; in the Eastland, conifers grow up to an altitude of 900 metres and deciduous trees (birch) to 1100 to 1200 m.

The conditions of working are facilitated to a considerable extent by the long winter with its settled weather and good transport conditions, and by the many water-courses which are suitable for carrying timber. The working of the forests therefore, in spite of the mountainous character of the country, may be described as easy. Owing to the great extent of the forest area, a comparatively large number of workers can be employed on the land during the whole year, for the work in the woods is chiefly done in winter, while the summer is the busiest time for agriculture.

The output of the forests far exceeds the country's own requirements and there is thus a large export of timber and other forest products, especially wood-pulp and paper. In the last few years, the annual export of timber has risen to about 1,300,000 cub.m; 700,000 tons of wood-pulp; and some 200,000 tons of paper and cardboard. There are in Norway 119 wood-pulp mills, some of them very large, and a great number of saw-mills and planing mills.

Most of the forests (about 84 %), are in private ownership, 48 % belonging to farmers, while 36 % are worked independently of agriculture. About 16 % belong to the State, and other official or semi-official institutions.

The work of the Government for the advancement of forestry and agriculture comprises; the official measures put into operation by the State Administration for agriculture and forestry: the work that is carried on by agricultural and forestry associations; forestry instruction.

The Department of Agriculture has 2 divisions, each of which has its executive Chief: 1) The Agricultural and Concession Division; 2) the Forestry and Veterinary Division. The latter has the following branches: Forestry, Reindeer and Freshwater Fisheries, Land Re-distribution, Veterinary.

All public administration relating to forests and forestry comes within the purview of the Forestry Office. The Director of Forestry is in charge and stands in the same position towards the Department as the Director of Agriculture. In addition to the administration of the woods and forests in general the Director of Forestry is responsible for the business management of the forests belonging to the State which comprise a comparatively large area, as will be seen below. The Office is divided into a technical and a legal section, as in the case of the Agriculture and Production Offices. Under the Forestry and Veterinary Division are 3 Forestry Inspectors of whom, however, 2 only have offices in the Department.

The Agricultural Societies are grouped in an Institution known as "Det norske Landbruksraad" (The Norwegian Agricultural Council), in which "Det norske Skogselkap" (The Norwegian Forest Society), and the "Norske Skogeierforbund" (Norwegian Forest-Owners' League), each have 2 representatives.

In addition to the 3 Inspectors of Woods and Forests mentioned above, 40 forest-managers, 20 assistants and about 500 wood-rangers are under the Control of the Director of Woods and Forests, all of whom are entirely in the service of the State. The Director also has the control of the following Bureaux that are carried on entirely for State purposes: The State Forestry Valuation Office: this office regulates the boundaries, and makes surveys, valuations etc. of the public forests and of the forests offered for sale to public Authorities. The permanent Staff consists of 2 forest valuers with 4 assistants.

The National Valuation Office for Forests, has been established for the purpose of furnishing, by means of direct measurements and investigations, statistics regarding the Norwegian forests. Its work consists in the first place in supplying answers to the following questions: 1) the area of forest and its distribution according to the different species and qualities of timber; 2) the existing supply of growing timber; 3) the amount of the current yearly increase, etc.

The work in the field proceeds by counties in the form of lineal valuation.

The permanent Staff of the National Forestry Valuation Office consists of 2 forest valuers together with the Office Staff. The other officials for the field-work are engaged every season.

According to the general scheme, the valuation is to be completed in the course of 5 years, for 9 of the largest forest-growing counties in the country. During the same period, the census of the forestry industry is to be carried out throughout Norway in order to ascertain the annual production of all the forests in the country and the consumption for household purposes. In this connection, returns are collected from all the forest properties in Norway giving the output for 3 consecutive years.

The State founded in 1917 an Experimental Station for Forestry at Aas near Christiania. The Staff at present consists of 2 experimentalists and 2 clerks.

There is also an Experimental Station for Forestry affiliated to the

Bergen Museum, the principal contributor to its support being the Norwegian Forestry Society.

The State supports in various ways the work required for the preservation and renewal of the forests. Large nurseries of plants for sale have been established in various parts of the country. The State has also erected seed drying-rooms in several districts.

Since 1872 the State has been planting the treeless wastes in Vestland and has regularly carried on cultivation work in its own forests. It has planted altogether on the moors of Vestland 3709 hectares of forest, which has, generally speaking, thriven very well. The State also makes grants for private plantation and for plantation carried out by local authorities. The latter can also obtain for the purchase of ground for planting, loans free of interest and of repayment of principal for 30 years.

In regions that are poor in woods, and in districts where it is to be feared that the forests, owing to their northerly situation or great altitude may die out if neglected, the State aims, if possible, at acquiring the forests to secure their preservation.

The Norwegian Forestry Society ("Det norske Skogselskap"), founded in 1898, is one of the Forestry Associations with a semi-official character; it depends partly upon private funds and partly upon grants from the State. Its objects are to diffuse information regarding the afforesting of treeless tracts and the advancement of Norwegian forestry in general. Dependent upon this Society are the local forestry societies (1 in each county). The County Forestry Societies have in their service about 50 fully qualified officials who give gratuitously to forest owners advice on all matters concerning forestry, in the same manner as an Agricultural Official gives advice on agricultural questions.

Through the forestry societies the State gives grants for the planting of forests both to private owners and local authorities.

The Norwegian Forest-Owners' Union is an amalgamation of the local associations of forest owners which are to be found in most of the forest districts throughout the country. It was founded in 1913, with the object of protecting the common interests of forest-owners, especially as regards the sale, transport, measurement and floating of timber. The Union also gives assistance in all the more important legal questions and other matters of special importance for forestry.

Pursuant to the law of July 1, 1887 concerning the utilisation of the water-courses, those persons on whose account timber floating on a river is conducted are entitled, when the majority of them are agreed, to decide that the floating shall proceed in common and under joint management, as well as to lay down the rules under which it is to be carried out. In order that decisions regarding the adoption of a joint scheme of floatage, or alterations in the adopted rules may be valid, the majority must represent at least  $\frac{1}{3}$  of the quantity of timber floated on the particular water-course during the preceding year. The rules are subject to the approbation of the King in Council. These combinations are called Associations for Joint Floatage and have been established along most of the great water-

courses of the country, and by improving the river channels a great impetus has been given to the work. Expenses are covered by a charge upon the timber transported.

Until recently, the purchaser himself prescribed the rules for the dimensions of the timber he bought and was responsible for the measurements taken; hence in many cases, the seller was more or less at the mercy of the buyer. In order to secure a more equitable arrangement there have been established of late years, along the main water-ways, special institutions with permanent and sometimes attested measurers, who receive timber on behalf of the buyer. These institutions are called Associations for Measuring Timber and their establishment is quite voluntary. They have a Council of Management to which one half of the members are elected by the buyers and one half by the sellers, the buyers and sellers each bearing half the cost.

The Norwegian Mutual Forest-Fire Insurance Company was founded in 1912 by the Norwegian forest-owners. The Company insures the forests for a premium of 1.25 per 1000 of the sum assured in cases where forest-fire regulations have been introduced. Where such regulations have not been established the premium is 1.75 per 1000. After a period of insurance for 4 years, a reduction of 20 % is made in the premium. After a further 4 years, a reduction of 0.4 per 1000 is allowed in the form of a bonus. Most of the insured persons have thus an effective premium of 60 *øre* per 1000 *kroner* of the insurance benefit. Only the forest ground and the young wood are included in the insurance, but not timber trees. In 1920 about 65 % of the forest area of coniferous trees was insured in the Company to a total value of 259 124 000 *kroner*.

Other associations concerned with forestry may be mentioned such as: the Norwegian Timber Export Association ("Norsk Trelasteksportforening"), the Norwegian Pit-props Exporters' Association ("Norsk Propseksportørers Landforening"), the Norwegian Cellulose Association ("Norsk Celluloseforening"), the Norwegian Wood-pulp Association ("Den norske Tremasse forening") the Norwegian Paper makers' Association (De norske Papirfabrikanter Forening), and Norway's Timber Union ("Norges Trelastforbund").

The forest-owners have their own bank, the Forest-Owners' Bank ("Skogeierbanken") and a Cooperative Bank has recently been founded, The Norwegian Credit Association for Agriculture and Forestry ("Norges Kreditforening for Land og Skogbruk").

As regards Forestry Legislation, the law of August 8, 1908 for the preservation of protective woods and against the destruction of forests, with the supplementary law of June 7, 1916, may first be mentioned.

By virtue of these laws, rules have been established by Royal Order in Council for the hewing of timber in the various rural districts; these rules generally contain amongst other provisions, a clause prohibiting the cutting down of trees under a fixed minimum dimension, except where such under-sized trees are hindered in their growth, stunted, damaged or the like. The State allows one half of the expenses incurred in se-

curing the proper observation of the law. In districts where the local authorities have not of their own initiative passed bye-laws, the general regulations fixed by the supplementary law of June 7, 1916, hold good.

The Act of July 14, 1893 regarding restrictions on the use of fire in woods and fields etc., with the amending Act of 1921, lays down certain restrictions upon the use of fire in forests and enjoins upon the district Authorities the enactment of so-called "forest-fire regulations" According to these regulations, every able-bodied man in a district may be called upon to assist gratuitously in extinguishing forest-fires.

Amongst other laws may be mentioned, the Act of May 20, 1899 regarding the hunting and snaring of game; the Act of July 20, 1918 regarding the housing of men and horses engaged in forest work and timber floating. The so-called "Mountain Law" of March 20, 1920, gives to the local Authorities in the highlands the power of regulating for the parishes their fishing, hunting and pasturing rights on the commonlands belonging to the State, including also the common forest-lands; while the Act of August 20, 1915 forbids the separation from the farm-holdings of the forest and mountain tracts necessary for working the farm.

By a number of laws enacted from 1906 onwards various restrictions have been imposed upon the free right of acquiring water-falls, mines, forest, land and mountain properties, lime-pits, peat-bogs and certain other national assets.

As regards Forestry Instruction, the High School of Agriculture for Norway includes a Forestry Section and owns an estate and some forest-land on which experiments are carried out. Instruction in Forestry is also given at the Lower School of Agriculture, and in 5 State and 3 County Forestry Schools, where the course lasts for 1 year, and at 2 County Forestry Schools, attached to agricultural schools, with a 1 ½ year's course.

For the financial year, July 1, 1921 to June 30, 1922, the Forestry Service budget was as follows: Expenditure 10 821 000 *kroner*; income 7 823 292 *kroner*. In these figures are included the expenditure and income for all forests administered by the Director of Forestry, as well as contributions to the State and County Schools of Forestry and to the Norwegian Forestry Society.

G. A. B.

440 - **Effect of Orientation upon the Success of the Transplantation of Forest Trees.** — MARTIN ZÉDÉ, in *Comptes rendus de l'Académie des Sciences*, Vol CLXXIV, No 1, pp. 61-63. Paris, January 3, 1922

When making plantations of different species of trees (firs, spruces, larches and birches), in the island of Anticosti, the author found that if the orientation of the trees was not changed, the number that did not take root was greatly diminished (from 50 % to 6-8 %). This phenomenon was perhaps more noticeable owing to the inclement climate of Anticosti (Canada).

In practice, before moving trees, it is necessary to notice their orientation, in order that when transplanted, they may be arranged in such a manner that the parts which originally faced north, may again have the same direction.

G. A. B.

441 - **Paraguay Timber Industry.** — *The Board of Trade Journal*, Vol. CVII, No. 1313, p. 104. London, Jan. 26, 1922.

The growing importance of the timber industry of Paraguay may best be gauged by the following figures showing the exports of timber during the last five years:—

Year	Logs		Sawn Timber	Pence Posts	Spacers	Quebracho Logs
	Rough	Trimmed				
	Tons	Pieces	Cub. M.	Pieces	Pieces	Pieces
1916 . . . . .	8 608	33 000	1 315	52 513	544 221	1 006
1917 . . . . .	38 995	39 000	1 777	47 586	1 026 066	1 605
1918 . . . . .	47 710	47 228	4 533	24 980	1 234 717	522
1919 . . . . .	51 821	41 171	3 848	52 841	1 135 724	1 668
1920 . . . . .	47 222	63 314	5 852	60 281	3 138 426	269

The export of quebracho logs has greatly declined since the war, and the production is now almost totally absorbed by the tannin factories. No quebracho grows in Eastern Paraguay and the industry is confined to the Chaco Territory. The average quantity of extracts of quebracho exported during the last seven years is 24 027 tons a year (maximum 32 976 in 1919 and minimum 12 710 in 1914). G. A. B

442 - **The Timber of India and Burma** (1). — HOWARD, A. L., in *Journal of the Royal Society of Arts*, Vol. LXX, No. 3613, pp. 238-248, figs. 6. London, Feb. 17, 1922.

The author made an extended tour in 1921 through some of the chief timber-producing areas of India, Burma and the Andaman Islands, with the object of gauging their possibilities for trade development.

From nearly 2500 different species to be found in these forest areas only a small proportion are of economic interest, and scientific knowledge concerning them has up till now been limited and very few of the trees have been known to timber buyers elsewhere. The somewhat vague term "teak and jungle-woods" has in many cases proved detrimental to the trade, seeing that in these so-called "jungle-woods", logs of much value are to be found superior even to the finest mahogany, or satin wood, and boxwood known.

The author has selected a few of the most outstanding specimens, and describes their commercial value (2).

1) Laurel wood, *Calophyllum Inophyllum* Linn — a dark reddish-brown wood with a handsome wavy grain. Its durability compared with walnut, for which it may prove be an excellent substitute, may be regarded as beyond question.

2) Gurjun (*Dipterocarpus turbinatus* Gaert) and other *Dipterocarpus* spp.. Found in Burma, Chittagong and the Andaman Islands. This

(1) See *R. Jan.* 1919, No. 1. (Ed.)

(2) Supplemented by notes on the given specimens taken from *Timbers of the World* by A. L. HOWARD, Macmillan Co. 1920)

timber is available in very long lengths and large sizes, free from any defect, and according to the results of the breaking tests, it has proved to be stronger than oak (*Quercus pedunculata* Ehrh. and *Q. sessiflora* Sm.). It is apparently not possible to break the wood right through; two pieces continue to remain jointed together by what appears to be a tough outer skin which forms a kind of hinge. For joinery and carpentry work etc. the wood should first be thoroughly seasoned and whenever possible sawn on the quarter, which prevents shrinking. It makes a beautiful flooring and has also been utilised advantageously for panelling etc.

3) Indian Silver greywood. This varies in shade, but possesses a permanent coloration, in which respect it differs from the so-called "greywood" or stained sycamore which up to the present has been so much in use. A careful selection of the different colour varieties gives a very harmonious effect for parquet flooring, furniture etc., and the commercial value is highly estimated.

4) Pyinkado (*Xylia dolabriformis* Benth) — the iron wood of Burma, hard, heavy, strong and durable. The thick oily substance in the pores has a tendency to exude on to the surface after the wood has been worked which may be conducive to durability, but has certain drawbacks when the wood is used for flooring.

The wood is chiefly used for railway sleepers, but it has also proved very valuable for building purposes. Though it is so hard, it can be sawn and worked without much difficulty when comparatively fresh.

5) Padauk (*Pterocarpus* spp.). — The Andaman padauk (*Pt. dalbergioides* Fock.) (syn "vermillion wood" and "East Indian mahogany") — very strong and durable, hard and firm, does not split, shrink or expand with any climatic change; the wood possesses a brilliant lustre which distinctly adds to its commercial value when utilised for making furniture etc.

The padauk of Burma (*Pt. macrocarpus* Kurz.) is of a duller colour, but possesses strength, toughness and elasticity to a marked degree.

Both types of padauk have been approved by the Admiralty as a substitute for "sabicu" (*Lysiloma Sabicu* Benth) in the construction of battleships.

6) Indian Boxwood (*Canthium didymum* Roxb.). — A shipment of this boxwood recently examined, contained two different kinds of wood, one type which apparently does not split in the log or when cut up, or after manufacture, and the other which is liable to split under all these conditions. The great value of the first type is evident.

It should be noted that neither the Indian boxwood nor the West Indian sp. *Tecoma pentaphylla* Juss come under the genus *Buxus*.

7) Haldu (*Adina cordifolia* Hook) — in India, Burma and Ceylon — noted for the remarkable quality of the grain, smooth texture, durability and attractive colour, is worked very easily and does not split; it is also readily adaptable for chair making, carving, brush work etc. — and for shuttles and bobbins.

8) Koko (= East Indian Walnut) (*Albizzia Lebbek* Gamble) — re-

markable for its handsome colouring and good shape ; its durability is excelent.

9) Pynima (*Lagerstroemia Flos-Reginae* Retz) — a magnificent timber hitherto almost entirely overlooked, but probably a more valuable wood in its general qualities than any timber, for example, in the whole of North America. In India it is not as valuable as teak, as it is only partially resistant to attacks of white ant., in Europe however the author considers it ranks almost as high as teak. Its great reliability, coupled with excellent qualities of texture and grain, places it on a very high level for decorative wood work.

10) White Bombwe (*Terminalia procera* Roxb) — a very strong wood with firm, hard and close texture. Although there appears to be scarcely any actual demand in India, it should not be assumed that it cannot be utilised advantageously elsewhere. It should be borne in mind that the chief factor which determines the use of wood in India is its resistance to white ants, dry rot etc — points which are not of importance in other countries.

11) White Mahogany ("Prima Vera"). Source unknown (native of Central America) — a wood possessing a smooth, silky surface and very easily worked ; light weight but strong enough for fittings, fixtures in cabinet making, joinery and ship-building.

Attention is drawn also to the coral wood ("bois de corail") of the Andaman Islands, sissoo (*Dalbergia Sissoo*) which has been successfully used for fine cabinet work, and thitka (*Pentace burmanica*) which resembles Cuba mahogany.

443 - **Determination of the Value and Uses of the Various Timber and other Forest Products in British North-Borneo** (1). — SMITH, MIDDLETON, in *The Engineer*, Vol. CXXXII, No. 3444, pp. 710-711. London Dec. 30, 1921

There seems to be a continuous demand for Borneo Timbers and it was decided to make a series of tests to discover the properties and values of various samples hitherto insufficiently known outside Borneo, in order to satisfy the demand more adequately. There can be located within this belt, a number of blocks of 50 000 acres on which the stand of marketable timber will average 2 000 cub. ft. or more per acre. Estimates based on 169 342 acres on the East Coast show the average stand to be 2613 cub. ft. per acre, the two species occupying the greater part of the stand being the "Seriah" or Borneo cedar (*Hopea* sp.) which is the most abundant timber of North Borneo, and the "kruen" or "apitong" (*Dipterocarpus grandiflorus* Blanco) a timber suitable for constructional work, and suggested as useful for gun-stocks.

From the results obtained from the tests it was found that all the samples were more resistant to bending than crushing. The following were classed as hard woods and their average coefficient of bending strength was determined as follows :

(1) See *R.* April 1919, No. 476. (Ed.)

"Selangan batu" 8.06; billian (Borneo iron wood) (1) 7.29; "mirahow" (2) 6.77.

The following were classed as soft woods:— "greeting" 4.92; camphor wood (3) 4.93; oba sulu 4.92; orat mata 4.57; kruen 4.45 (4); kacha 4.24 and red serayah (5) 3.54.

A number of preliminary tests were made on samples of local woods in order to determine the most satisfactory method of loading and the best method of measuring deflections.

As a result of the tests for uniformity, the selangan batti was found the most uniform and after this the "oba sulu" and red "serayah". The crushing strength of each was within 10 % the mean value.

The results of the bending and compression tests on samples submitted by the China Borneo Company are given in tabular form

444 - **Studies on Foot and Mouth Disease in France** (2). — I SCHEIN, Dualité possible de la fièvre aphteuse, in *Comptes rendus de l'Académie des Sciences*, Vol. 174, No. 3, pp. 204-206. Paris, January 16, 1922. — II VALLÉE H. and CARRÉ A., Sur l'immunité anti-aphteuse *Ibidem*, pp. 207-208.

I. — As a working hypothesis, SCHEIN suggests that the name of foot-and-mouth disease has been given to two quite different maladies. Both are self-immunising, but neither are reciprocally immunising. True foot-and-mouth disease (aphthic fever), would appear to be contagious to man and pigs, or to one or other only, whereas "aphthoid fever" (the other disease), cannot be contracted by human beings or swine, or any other animal that is not subject to aphthic fever.

II. — VALLÉE and CARRÉ give reasons to explain the instability of anti-aphthic immunisation and also raise the question of the plurality of aphthic viruses. F. D.

445 - ***Solenopotes capillatus*, a Sucking Louse in Cattle, hitherto unknown in the United States.** — BISHOPP F. C. (Entomologist, Investigations of Insects affecting the Health of Animals, Bureau of Entomology, U. S. Department of Agriculture), in *Journal of Agricultural Research* Vol. XXI, No. 11, pp. 797-801, figs. 6 Washington, September 1921.

*Solenopotes capillatus* n. g. and n. sp. was described in 1904 by ENDERLEIN; this parasite was found on cattle in Leipzig. The author has discovered that the species has a wide distribution in the United States. He describes its life-cycle and states that, unless the measures necessary for its control are taken, it will become a serious cattle pest. F. D.

446 — **Diseases and Parasites of Sheep in Syria.** — See No. 457 of this Review.

447 — **Stomoxes as Carriers of Dromedary Trypanosomiasis.** — SERGENT, E. and DONATIEN, A., in *Comptes rendus de l'Académie des Sciences*, Vol. 174, No. 8, pp. 581-583. Paris, February 20, 1922.

The authors, as a result of observations and experimental researches, have come to the conclusion that dromedary trypanosomiasis is naturally transmitted in two ways: 1) in the open country, in the wheat fields by gadflies, for the larvae of these insects swarm in the damp sand of the valley bottoms; 2) in inhabited places (caravansaries), by stomoxes, for the straw litter in the stables harbours many of these pests. (The authors have found stomoxes in all the regions of North Africa, the coast, high-plateaux and the Sahara).

The trypanosomes do not develop within the insects, but are merely mechanically transported by them acting as carriers conveying the micro-organisms lancetwise on the exterior of their proboscis.

For the spread of the infection it is necessary that the insects should sting an animal suffering from trypanosomiasis in such a manner that the puncture bleeds, and then immediately sting a healthy individual. As trypanosomiasis is a disease of long duration in the dromedary, this animal acts as a reservoir of virus.

448 — **Experimental Researches on the Effects of Castration.** — LEINATI, L. (Istituto di Patologia comparata della R. Scuola Superiore di Medicina Veterinaria di Milano), in *La Clinica veterinaria*, vol. XLIV, No. 21-22, pp. 635-647 bibliography of 18 works, Milan, November 15 and 30, 1921; Vol. XLV, No. 1, pp. 14-30, bibliography of 48 works, January 1922.

ANATOMY AND  
PHYSIOLOGY

I. — **LEUCOCYTIC PHAGOCYTOSIS IN CASTRATED ANIMALS.** — The author gives a brief sketch of some of the most important researches made on this subject, before proceeding to a detailed account of his own experiments (on adult dogs) the results of which lead him to conclude that castration causes a decrease in the phagocytic index of the leucocytes. This effect is the same whether both or only one testicle is removed; in the former case, however, it is less marked and tends to disappear after a certain time, whereas in the second it persists without any change for 80 days after the operation.

The endoperitoneal inoculation of testicle extract into animals from which both testicles have been removed at once causes a rise in the value of the phagocytic index, but this does not last long and 24 hours later it falls to its previous level.

II. — **HAEMATOLOGICAL OBSERVATIONS ON CASTRATED ANIMALS.** — This article gives a rapid review of the many works dealing with the effects produced on metabolism, the tissues, the functional correlations of the genital and other glands, the active protective mechanism against disease (phagocytosis, serological reactions etc.), and also describes the author's own observations as to the red and white corpuscles, both from the quantitative standpoint (absolute and relative estimate of the number of these bodies), and from the qualitative (morphology and structure of the corp-

uscles). The animals used in the experiments were dogs. The results obtained lead to the following conclusions:

1) Castration has no appreciable effect, either quantitative or qualitative, upon the red blood corpuscles, nor upon the total number of the white corpuscles. This applies equally to monolateral and to bilateral castration.

2) The castration of adult animals produces on the other hand very noticeable and durable changes in the relative quantity and ratio, of both kinds of corpuscles, and causes:

a) a considerable decrease in the lymphocytes; b) a certain diminution in the number of acidophilous, polynuclear leucocytes; c) an increase in the large, mononuclear leucocytes; d) a certain increase in the basophilous, polynuclear leucocytes; e) a very noticeable increase in the neutrophilous, polynuclear leucocytes.

3) The effect of castration upon the relative number of leucocytes is more evident in the case of bilateral than of monolateral castration. The results, which manifest themselves very quickly, have a certain tendency to become permanent.

F. D.

449 - **The Possibility of Castrating Animals by the Use of Serums.** — GIULIANI, R. (R. Scuola Superiore di Agricoltura, Portici), in *Giornale di Agricoltura [della Domenica]*, Vol. XXXI, No. 30, p. 306. Plaisance, September 25, 1921.

The author has studied the possibility of substituting "biological" for surgical castration effected by the application of the principle forming the basis of cytolytic serums. The laboratory experiments hitherto carried out have given encouraging results. These experiments were directed to the preparation of a rabbit orcholytic serum. A he-goat was used to supply the serum; periodic injections of the solution of nucleoprotein, from the testicle of the rabbit being made in constantly increasing doses. The serum thus obtained was injected into rabbits; 3 to 4 cm. were injected each time at intervals of 8 to 5 days. 15 days after the first treatment, the testicles were already perceptibly atrophied, and the seminiferous ducts, although still recognisable, contained a kind of granular detritus. By prolonging the action of the serum for 30-40 days, a progressive atrophy (of the testicle glands was produced; these were to a large extent empty, and consisted of albuginea, interstitial connective tissue and a little much modified parenchymatous matter, in which the seminiferous ducts could with difficulty be distinguished.

F. D.

450 - **The Rejuvenescence of Animals; Experiments on Old Fowls and Doe-Rabbits.** — CHARON, A. G., OINENÉ, G., and YONENO, G., in *Journal d'Agriculture pratique*, vol. 55, Part. II, No. 48, pp. 454-457, figs. 4. Paris, December 3, 1921.

CHARON in his paper recalls: 1) the discovery of BROWN-SÉQUARD (1869), that all the glands, whether provided with secreting canals or not, supply to the blood certain useful principles, and that when the glands become less active in consequence of accident, disease or old age, the absence of these products makes itself at once felt; 2) his experiments in rejuvenating old persons (increasing their muscular force, cerebral exer-

tion and general vigour) by means of the injection of the testicular fluid of rabbits, or guinea-pigs.; 3) the opotherapeutic measures based on the knowledge thus acquired — 4) the experiments of WORONOFF (Directeur de la Station expérimentale du Collège de France), on the rejuvenescence of animals by grafting pieces of testicle taken from still younger animals. Stress is also laid on the value of the application of these methods to farm-stock, if they were easy of execution, and the author publishes a communication sent to him for insertion in the *Journal d'Agriculture pratique* by Yasusi OINONÉ (Director of the Oinoné Institute of Agricultural and Biological Research at Ogawa, Japan), and YONENO (Aviculturist of the Oinoné Institute).

These authors mention the rejuvenescence methods devised by STEINACH (*Archiv für Entwicklungssmechanik.*, vol. XLVI, 1920), and by SASAKI (of the Faculty of Medicine in the University at Kyusin). The methods suggested by STEINACH consists of the removal or ligature of the vasa deferentia, and that of SASAKI in administering, through the mouth an extract of the thyroid gland. They afterwards describe their own experiments, carried out according to the SASAKI method on old fowls and doe-rabbits. White Leghorn fowls of 6 years of age were given fasting, once daily at 6 in the morning, 0.03 gm. of dry extract of thyroid gland. The results were entirely satisfactory, as is shown by Table I. One of the birds which had only laid 25 eggs in 1915-1919, laid 129 in 1921-1922. The hens thus treated also became youthful in appearance; their skin grew fine and soft, their combs delicate and bright red and their movements were full of vigour.

TABLE I. — *Rejuvenescence experiments*  
with fowls of six years of age, March 31, 1920.

Length of treatment	Number of eggs laid	
	From Sept. 1 1918 to Aug. 31 1919	From Sept. 25 1920 to Sept. 24 1921
	without treatment	With treatment
15 days . . . . .	22	68
15 days . . . . .	28	50
30 days . . . . .	24	99
30 days . . . . .	29	103
40 days . . . . .	25	129
40 days . . . . .	26	105

Excellent results were also obtained with the doe-rabbits (Belgian breed); the data are given in Table II. Their appetite increased, they regained a youthful appearance, their fur became thicker, and they showed symptoms of heat and all but one (No. 2), were fertilised.

CHARON draws attention to the fact that it is quite conceivable that the thyroid extract, by exciting the reproductive functions, would stimu-

TABLE II. — *Experiments in the rejuvenescence  
7-year-old Doe-Rabbits, in 1919.*

No.	Duration of treatment	No. of young in litter produced after treatment	Appearance of animal after treatment
1. . . .	10 days	3	Slightly younger looking. Little vivacity
2. . . .	10 days	0	Rejuvenated; very lively
3. . . .	25 days	7	Much rejuvenated; very lively
4. . . .	25 days	5	Much rejuvenated; very lively

late egg production in fowls that are fairly good layers. The treatment can be carried out by giving in the morning, thyroid gland, or iodo-thyrine, mixed in suitable doses with a light paste. F. D.

#### HORSES

451 — **Horse-Breeding in Czecho-Slovakia.** — *Bulletin of the Ministry of Agriculture of the Republic of Czecho-Slovakia, Year II, No. 3, pp. 23-24. Prague, 1921.*

The breeding of horses for agricultural purposes is organised by the Ministry of Agriculture. The Military Authorities also have Stud Stations for breeding Army horses. The horse-breeding establishments are (except in rare cases), military institutions, and under the management of Stud Officers, or of army veterinaries. The Staff is composed of soldiers and civilians, except at Kladruby, where the Stud Station (the former Stud Station of the Emperor of Austria), is entirely managed by civilians.

In Bohemia, the horse-breeding Stations are at Domazlice, Nemošice and Písek. In these establishments stallions for use in the country only are bred, but at Nové Dvory, there is a State Horse Rearing Station where the young stallions bought from horse-breeding farmers are reared to supply the State Stud Station. At Kladruby, there is a similar establishment which is better suited to the purpose, as mares are also available whose foals have been weaned. In Moravia, the State Stud Stations are at Hodonín and Zlín — in Silesia, at Opava — in Slovakia, at Nitra, and Prešov — and in Sub-Carpathian Russia, at Turg-Kemety. Another Stud Station has recently been established in Slovakia.

In Bohemia and Moravia spirited, more robust horses of the oriental type or pure-bred English horses are bred for improving the blood. In the Czech countries farmers prefer the Ardennes or Noric breeds; in Slovakia, the oriental or the Noric, horse is the favourite. In Pre-War times, the interests of the army ranked before the farmers' with the result that the requirements of agriculture have not been satisfied.

In Sub-Carpathian Russia in the mountainous districts small robust "hucul" horses of a Polish breed are the best suited, and most in demand, for agricultural purposes.

In the Republic of Czecho-Slovakia, horse-breeding is organised in such a manner that the countries are divided into two districts. In the first, light mettlesome horses only may be reared, and in the second, only the heavier breeds. The zones are determined after some years have elapsed, according to the number of mares belonging respectively to light or heavy breeds to be found, as reported by the Commission under the control of the Ministry of Agriculture.

The Chambers of Agriculture, in conjunction with the Ministry of Agriculture of the former Monarchy, have supervised horse-breeding and collaborated with the Stud Stations for the disposal of stallions that are unsuitable for sires, in making Service Stations in the different districts, supplying stallions for private breeders, etc.

The service season for the mares lasts from February 1 to June 30. The Service fee is 200 crowns. In Bohemia, there are 130, in Moravia 80, in Silesia 30, and in Slovakia 120 special Stations with from 1 to 10 stallions at the disposal of horse-breeders, the State paying the rent. In addition there are private Stations which are only kept open in the same place for 4 years for the 2 types of breed.

The number of State stallions is estimated at 600 in Bohemia (half being of each type), 450 (in the same proportion) in Moravia and Silesia, 420 in Slovakia (where almost all are of the lighter type), and at 60 (light-type) in Sub-Carpathian Russia, that is to say the State possesses altogether 1510 stallions.

There are only about 240 stallions belonging to private individuals. These animals must have a Government Service Licence according to the decree of 1874 in Bohemia and to the law of the country (1905), in Moravia. A new law is being framed to establish other horse-breeding districts.

The most famous private Stud Stations are those of Baltazzi (Napajedla), Sailern (or Lukov, in Moravia where Belgian and English breeds are reared), Schwarzenberg (or Hluboká; English pure bloodstock), Baur (Pohled), Kinsky (Lysá n. L.), etc.

In Bohemia and Moravia, there are Unions and Cooperative Societies for breeding heavy blood animals or horses of the Noric breed. The Czechs prefer the Belgian and the Noric breeds. The Czech cooperative Societies are very prosperous and are able to buy and import foreign horses without any grant from the State. The Unions of the native breeders are at Sv. Dvory, Breznice, Pardubice, Benesov (light type), Caslav, Opocno, Prepychy, Belohrad, Budejovice, Netolice (heavy breeds) etc. In Moravia, the Horse Breeders' Union includes 38 Czech Societies (20 for the breeding of light and 9 for the breeding of heavy horses), and 7 German Societies; 4000 mares are registered on the Stud-Books.

The chief horse-markets are at Budejovice, Benesov, Netolice, Chrudim, Usti n. L. Horse-races are held at Prague, Bratislava, Pardubice and Karlovy Vary.

In pre-war Austria in 1866 the direction of horse-rearing passed from the control of the Ministry of War to the control of the Ministry of

Agriculture, but the Stud Staff still remained military. Any special questions were referred to the Ministry of Agriculture, but the staff was under the Ministry of War. The reason of this divided authority was financial. The valuable animals reserved for breeding-purposes could only be entrusted to reliable persons, i. e. to disciplined soldiers. Since however the Stud Stations were under the authority of the Ministry of Agriculture, the interests of agriculture received special consideration. This Ministry could always rely upon obtaining the collaboration of the horse-breeding farmers, and allowed them consultative powers as regards questions related to horse-breeding through the medium of the local commissions appointed in all the Provinces.

452 - **Study On Horse Breeding in the United States.** HARPER M. W. in *Cornell University Agricultural Experiment Station Bulletin* 403, 49 pp., figs. 17. Ithaca, New York, 1921.

The object of these researches which were begun in 1909 and continued for 10 years, was to obtain data on the breeding of foals, in order to prevent the losses due to failure of conception, or easily preventable diseases in the mare.

The observations which were made on 34 brood-mares, used chiefly for agricultural work, and to a small extent for hauling coal, lasted in the case of the mares from the time of service until weaning, and the foals, from birth until maturity was reached. The studies include the rations to be given to a foal, the amount of food required, the development attained, the cost of rearing.

The 34 brood-mares studied (Percherons, half-bred Percherons, pure bred Hackneys), produced as the result of 144 matings, 83 living foals counting one set of twins, 17 foals died shortly after birth. The gestation period varied between 316 and 361 days, the average being 333 days. The duration of the gestation period was on an average 4 days longer for colts than for fillies varying from 317 to 361 days (average 335), and from 316 to 357 days (average 331) respectively. In the case of 171 brood-mares under observation in addition to those forming the subject

of the experiment, the average length of the gestation period was 335 days and the difference in the case of the two sexes was scarcely one day.

The author has drawn up Tables relating to the winter-feeding (from October 9 to May 8), of 66 just weaned foals, 53 foals of over one year of age and 46 two-year-olds. The average consumption was in the first group, 551 kg. of grain + 724 kg. of hay, or 4.8 kg. of grain + 6.3 kg. of hay per kg. of increased live-weight; in the second, 684 kg. of grain + 1150 kg. of hay, or 8.7 of kg. grain + 14.6 kg. of hay; in the third, 862 kg. of grain + 1267 kg. of hay, or 25.6 kg. of grain + 37.7 kg. of hay.

The rations given were: for sucking foals, a little grain 3 times a day, beginning with 100 gm. and gradually increasing up to 450 gm.; for weaned foals, 680 to 910 gm. of grain 3 times a day, and in addition, 1 kg. to 1.8 kg. of hay in the morning and 1.8 kg. to 2.3 kg. in the evening; for foals over one year old 1.4 kg. of grain in the morning 0.9 kg. at midday, and the same amount in the evening, as well as 3.6 kg. to 4 kg. of hay morning and evening; for foals above 2 years of age, 1.4 kg. of grain 3 times a day and from 4 kg. to 4.5 kg. of hay morning and evening.

If it is assumed that a sucking foal consumes 82 kg. of grain, the total amount consumed by a foal from birth until 3 years of age is about 22 quintals of grain and 31 quintals of hay.

The average weight of 66 foals at birth was a little over 52 kg., the 33 colts weighing 52.7 kg. and the 33 fillies 52.2 kg. The average weight (geometrical average) of 67 foals on May of the year following their birth was 345 kg., the average increase in the mean weight was 291 kg., or 553 % in 377 days from birth.

The average weight of 53 foals on May 9 of the year when they completed their second year, was 494 kg. showing an increase of 153 kg. over their weight in the previous year, or 44 % (409 gm. per head and per day). The decreased rapidity of growth was still more marked in the following year, on May 9 of their third year, the foals weighed on an average 576 kg. or 76 kg. more than in the previous year i. e., 15 %. If the weight at birth is subtracted, it is found that the foals had gained 524 kg. in 3 years, 291 kg. having been put on during the first 377 days. This shows the importance of insuring the rapid growth of the animals from the beginning. The above-mentioned data are a further confirmation of the statement that growth during the early stages of a foal's life is not only more rapid but obtained with the consumption of less food.

The cost of rearing a foal up to the age of 3 years is estimated as follows.

The author gives a large number of general rules for the feeding and management of brood-mares and foals.

On a farm devoted to horse-breeding, it pays best, as a rule, to purchase food in more or less large quantities. On a general farm, all the food consumed by the horses should be grown on the premises.

On farms where general crops are cultivated, and the horses have much hard work to do at the harvest seasons and when important operations are in progress, but are little used the rest of the year, it pays well

to employ mares, since the foals they produce make up for the days lost during foaling etc.

Keep and stabling . . . . .	20.00
Food (grain and hay). . . . .	108.64
Pasture . . . . .	15.00
<b>Total . . . . .</b>	<b>187.49</b>
Credit for work done from the age of 2 1/2 years. . . . .	29.15
<b>Net cost of foal at the age of 3 years. . . . .</b>	<b>158.34</b>

\* The mares continue working to within a few days of foaling as this has been found beneficial both for dam and off-spring.

Given that the net cost of rearing a three-year-old foal may be reckoned, as appears from the above, at about 160 dollars, and that the animal will fetch 225 dollars, a profit of 50 dollars viz., 30 % on the capital employed will be obtained. F. D.

453 - **Essays on the Depreciation in the Selling Value of Injured Horses. Permanent Lameness.** — NICOLAS F., in *Recueil de Médecine vétérinaire*, Vol. XCVIII, No. 2, pp. 71-80, Paris, January 30, 1922.

The damages to be paid by third parties who are responsible for accidents come under two heads: *compensation for temporary inability to work*, if lameness disappears; *compensation for actual depreciation* (which must be paid in addition to the first), if the horse is permanently lamed: The author considers the question of assessing this latter liability for which there is at present no guide.

The consequences of lameness are of two kinds: 1) economic; 2) physical.

1) *Economic standpoint.* — The lamed animal has lost its usual capacity for work owing to diminished speed, or increased fatigue.

The kilogram output per second (D'') is the result of the product of the animal in kilogrammes (E) and the speed per second in metres (V). —  $D'' = E \times V$ . As there are no existing data whether of an empirical or experimental character for measuring the decrease in V due to lameness, the decrease in the output cannot be directly determined.

The author avoids the difficulty by first calculating the pecuniary loss involved in a determined incapacity for work and obtains the following formula:

$$\text{Pt. r.} = g \times n \times (14 - a) \times \frac{i}{100}$$

where  $Pl. r.$  = loss of return;

$g.$  = daily return from animal after subtracting expenses of keep.

$n$  = number of work-days per annum.

$a$  = age of animal at the time of the accident (14 —  $a$  can however never fall below unity if  $a$  is 14, or higher);

$i$  = incapacity for work expressed in centimes.

Two cases may occur: *a*) incapacity for work involving a loss of output greater than the maximum possible depreciation of the horse (it is evident that it is the maximum depreciation that must be paid in compensation); *b*) a loss of return lower than the maximum depreciation, in which case the actual loss alone must be made good.

The maximum depreciation (Dp. m.) that a horse can undergo is given by the formula (1):

$$Dp. m. = Vba - P \times p \times c$$

$Vba$  is, other things being equal, the value of the horse before the accident according to the age ready-reckoner;

$P$  = the weight of the horse;

$p$  = the price per kg. of meat of the horse as it stands;

$c$  = a coefficient that is 1, if the animal is only fit for the butcher, and above 1 if the horse has still some work in it before it is slaughtered. According to some statistics relating to rejected army horses, the author has taken  $c$  as  $= \frac{10}{8}$ . This coefficient is, however, liable to variation according to the season, place, etc., which require to be determined. (2)

In order to calculate the loss of output due to a given incapacity for work, it is necessary in the first place to determine what amount of incapacity for work is produced by different degrees of lameness. Three such degrees may be considered: *a*) severe lameness, or when the animal has to go on three legs, causing an incapacity of 50 to 100 %; *b*) slight lameness, scarcely perceptible, causing an incapacity of 1 to 5 %; *c*) unqualified lameness, which is the most common; this the author divides into 2 categories: acute lameness causing an incapacity for work ranging from 20 % to 50 %, nearly always entailing the maximum depreciation; slight lameness, 5 to 20, which generally causes partial depreciation.

2) *Physical standpoint.* — The importance of the horse's lameness depends upon the use made of the animal. In saddle or trotting horses, it entails the maximum depreciation.

Owing to the serious economic results of lameness, the expert should in practice consider carefully in the case of a recent accident likely to

(1) See R. Feb. 1922, No. 189. (Ed.)

(2) See: NICOLAS: Points de repère pour l'estimation de la valeur des chevaux de réforme de l'Armée. (Points to be taken into account in estimating rejected Army horses), in *Recueil de Médecine vétérinaire* No. 17 p. 299, Sept. 15, 1921 — The sale price of a rejected horse does not depend upon its age. It is about  $\frac{3}{8}$  of the purchase price at the same date. The chief factor regulating the sale price is the weight of the animal;  $\frac{3}{10}$  of the total value of the horse is represented by its worth to the butcher, and  $\frac{2}{10}$  by its value as a work-animal. It is easy to calculate the former as a function of the price per kg. of the meat, of the weight and return (on an average 50 %), and all that is required, in order to ascertain the market value of the animal, is to multiply the butcher's estimate by  $\frac{10}{8}$ . (Ed.)

cause permanent incapacity for work, whether it is worth while to undertake any treatment. To decide this point, a comparative estimate must be made of the value of the horse on the one hand, and the probable cost and possible depreciation on the other. This can be done by means of the following equation :

$$\frac{\text{Maximum depreciation}}{\text{damage} + \text{loss of output}} = x$$

If the proportion is below or equal to unity it is economically useless to treat the horse, and its slaughter should be recommended. In any case, treatment is expensive and may prove unsuccessful; there is considerable risk that the outlay involved in 2 or 3 months' medical care, feeding, and the hire of a substitute will be thrown away upon a depreciated horse.

454 - **Lesbouyries' Pincers for Castrating Horses.** — LESBOUYRIES, in *Recueil de Médecine vétérinaire*, Vol. XCVIII, No 2, pp 53-44 fig 1 Paris, January 30, 1922

Castration by means of crushing the seminal cord is usually practised with an emasculator, or with REINER's pincers which have the advantage

LESBOUYRIES' Pincers.

age of affording great haemostatic security. The author, however, found that the grip of the crusher was not regular or always sufficient to insure haemostasis, and that after a certain number of operations, the knife deviated from the arm of the crusher, so that only an inadequate and unsatisfactory section was made. In order to remedy these defects, certain modifications were made in the pincers. The jaws are tightened by a rapidly-moving spring, instead of by a toothed-bar; the cutting-blade is made independent, by being mounted on a special screw; other minor alterations have also been made so that the instrument can be easily taken to pieces. The accompanying figure shows the instrument in its new form. F. D.

Ixelles-Brussels, August-September 1921. — VI COLOMBE M., Appréciation des qualités beurrières et laitières chez les vaches, in *Journal d'Agriculture pratique*, Year LXXXV, No. 44, pp. 377-379, and No. 45, pp. 391-393. Paris, November 1921.

X. — **CATTLE JUDGING AT SHOWS IN EAST FRISIA AND THE PROVINCE OF SAXONY (PRUSSIA).** — Cattle entered at Shows in East Frisia are judged according to LYDTIN'S method. The judge scores for milk conformation, head and horns, coat, colour, conformation, capacity, general appearance: 3 points mean excellent, 2 good, 1 mediocre, 0 poor that is to say, rejected. For milk conformation and general appearance the points are doubled. The perfect animal thus receives 24 points to which are added points for measurements (18 in the case of a perfect animal), or 42 points altogether.

Three points at the maximum are given for the following first 3 measurements taken together, and 3 for each of the others:

height: a) at withers; b) at centre of back; c) at point of withers; d) at insertion of tail: e) length and width: f) of chest; g) of pelvis; h) of haunch; i) depth of chest:

b) should not be less than a;

c) should not be greater than  $a + 8$  cm;

d) should not exceed  $a + 6$  cm;

e) in cattle 3 years of age should at least be  $a + \frac{1}{10}a$ ; in the case of older animals, it ought to be  $a + \frac{3}{20}a$ ;

f) at least  $\frac{1}{3}$  of a.

g) at least  $\frac{1}{2}a$ .

(1) See R. April 1921, No. 411. (Ed.)

Should the width of the chest and pelvis and the length and depth of chest exceed by 5 cm. the required measure, the animal is classed as good, if they exceed them by 10 cm. the animal is classed as excellent.

This method, in which the number of points depends upon the opinion of the judge and upon measurements, has been in vogue until recently, but the number of entries at the shows has now increased to such an extent as to make it impossible to carry out the measurements. For this reason, the "Gesellschaft für Züchtungskunde" (German Stock-Breeding Society), has taken the initiative in introducing a new scale of points to be adopted throughout North Germany.

In the new method of scoring used by the "Verband für die Zucht des Schwarzbunten Tieflandrindes in der Prov. Sachsen" (Union for Breeding Black Pied Netherland Cattle in the province of Saxony), a maximum of 100 points is credited to the ideal animal, each part being estimated by points 1 to 5, as follows: 5 = excellent, 4 = good; 3 = fair; 2 = mediocre; 1 = poor, rejected. The scale of points is as follows:

1) General appearance	5 > 4 points
2) Head, horns and neck	5 < 2 "
3) Shoulders, chest	5 < 1 "
4) Back, flanks, loin, paunch	5 < 2 "
5) Pelvis, croup, hip, insertion of tail	5 < 3 "
6) Thurl	5 < 1 "
7) Limbs, gait	5 < 1 "
8) Colour, skin, and coat	5 < 1 "
9) Udders and milk ducts in the case of cows, genital organs in bulls	5 < 2 "
10) Development, vigour	5 < - "
11) Pedigree	5 > 1 "
<i>Total</i>	100 points

KOPPE proposes putting general appearance at the bottom of the scale so as to summarise the preceding points.

II — METHOD OF CATTLE-JUDGING ADOPTED IN OLDENBURG. — Since 1909, only the offspring of registered animals may be entered on the Oldenburg Herd-book and these are subjected to a very strict examination, especially in the case of bulls. There is a supplementary register ("Hilfsbuch") for good cows born of unregistered parents, the female (but not the male) offspring of the cows entered on this register, if sired by a registered bull, may be entered after examination on the Herd-book. Registered bulls only are allowed by law to serve cows not belonging to the owners. The accompanying form is used in judging bulls (Table I).

This form is a modification of the one proposed by MÜLLER for the cattle of Jeverland.

TABLE I. — *Form used in Oldenburg in judging bulls.*

Name . . . . .  
 Date of calving . . . . .  
 Breeder . . . . .  
 Owner . . . . .  
 Date of examination . . . . . Place where examination took place . .

	Points	Remarks
1) Back line and position of tail . . . . .		
2) Length . . . . .		
3) Depth of chest, abdomen . . . . .		
4) Shoulders and width of flanks . . . . .		
5) Hips and pelvis . . . . .		
6) Thurls and hocks . . . . .		
7) Width of chest, position of shoulders and neck . . . . .		
8) Neck, head and horns . . . . .		
9) Skin and coat . . . . .		
10) Colour . . . . .		
11) Strength, shape and position of limbs . . . . .		
12) Gait . . . . .		
13) Vigour . . . . .		
14) Pedigree . . . . .		
15) Udders and signs of capacity for milk-production . . . . .		
16) General appearance . . . . .		

Points 5 = excellent, 4 = good; 3 = fair; 2 = mediocre; 1 = poor; 0 = very poor

Maximum of points = 90; minimum for acceptance, 54. For evidence of capacity for milk production, and for general appearance, double points are given

III. — METHOD OF CATTLE JUDGING ADOPTED IN JEVERLAND. — In the territory of the "Jeverlandische Herdbuchverein" (Union of Pedigree Cattle Breeders in Jeverland), bulls entered have been judged since 1861 in accordance with a law passed that year. Until 1901, the animals were judged only by the eye without any measurements.

Dating from 1893, many investigations have been carried out by means of measurements made with LYDTIN'S apparatus. The data obtained served to determine the normal development of the animals at different ages, and were taken by MÜLLER as the basis of his cattle-judging method which has been adopted in Jeverland since 1901. According to this method, 15 notes each of 3 points can be given for each animal viz.: 0: bad; 1 fair; 2 good; 3 excellent. The third note (general appearance) may have double marks, so that the points for the perfect animal will be 48. For admission to the herd book, an animal must obtain at least 28 points. If 2 out of the 3 judges see at a glance that an animal cannot be admitted, no measurements are taken and it is withdrawn. The points based on measurements are 5 in number: back line, length, width of pelvis at hip, width of chest, depth of chest. In each case the minimum dimensions admissible are fixed for the different ages of the cattle.

TABLE II. — *Form Adopted*  
by the "Deutsche Landwirtschafts Gesellschaft".

	Maximum Number of points	Points credited by each judge	Average number of points	Remarks
I	2	3	4	5

1) Signs of capacity for milk production	—			
2) Signs of capacity for beef production	—			
3) Signs of capacity for work	—			
IV. <i>General appearance</i> . . . . .	—			
<i>Total</i>	100			

\* In scoring for milk, beef and work in the case of different breeds, the market values must be taken into account

Since 1914, additional points are credited separately to cows for butter production viz.: for an annual yield of 100 kg. of butter, 1 point; for 125 kg and over, 2 points; for 150 kg and over, 3 points. Cows of less than 5 years of age received an allowance of 5 kg of butter. The production of the last year of testing or the average of the last two years is taken into account.

IV — STUDIES ON CONFORMATION IN RELATION TO MILK PRODUCING CAPACITY IN CATTLE (1). — Taking as his basis a large series of data collected by the American Jersey Cattle Club on the scores of cows inscribed in the Registry of merit, GOWEN has compiled a table giving the mean score and milk yield as scored by 19 different judges and also the mean annual milk yield of these groups of cows. In a second Table, he gives the standard deviation for the two average groups and in a third, the correlation between the score and the milk yield as shown by 19 different judges. The average correlation coefficient is 0.246. It is negative in 2 cases, and positive in all the others (leaving out the negative cases), from  $0.027 \pm 0.104$  to  $0.614 \pm 0.067$ .

These figures show the great influence of the personal equation of the cattle judge. Cows giving approximately the same milk yield have a difference of  $6.5 \pm 0.6$  points on score according to the decisions of two individual experts. No particular association is shown to exist

(1) See R. Oct. 1920, No. 1012 (Ed.)

between the variation of each judge in his total score and the variation of the cattle he judged as to their milk yield; there is on the contrary, a certain parallelism between the scores of several judges for different groups of cattle.

The judges differ not only in the mental scale by which they make their judgements, but also in their capacity for correct classification as regards milk yield and butter-fat percentage. Of the 19 judges considered in this paper, 9 were good, 8 mediocre and 2 inefficient, as giving better scores to low-producing cows than to high producers, and responsible for the two above-mentioned negative correlations. The average ability of this group of judges to score for milk yield is about 25 %, better than that of the average trained dairyman.

There is no relation between the average score given by each judge to his group of cows and his ability to value them for milk production. When it is noted that the mental scale of each judge differs considerably this fact is significant. It shows clearly why two equally good judges of cattle may place their cows several points apart, while at the same time, they keep the cows in the relative order of milk yield.

Cows whose average milk yields are larger or variable are more easily judged than those with a lower or uniform milk production. The scores of good judges show more variation than those of inferior judges.

Only about one man in two can pick out a good milker at sight. It is therefore necessary for a judge not to rely entirely upon his ability to select cattle by conformation, but to test the actual milk yield by weighing the milk. Even if the milk production of one week only is tested, the figures obtained are nearly twice as valuable as an indicator of milk production over a long period as a judgement based on the conformation of the cow, although this conformation be judged by men of considerable ability.

V. — JUDGING CATTLE AT SHOWS. THE IDEAL TYPE OF CATTLE FOR BELGIUM. — The new method of judging cattle by points, instead of by general appearance, has not given the results expected in Belgium.

Seeing the great importance that the points method may have for the progress of cattle-breeding on Belgium, MARCQ and MAHY have made a study of its adaptation to judging Belgian breeds and consider; a) the systematic use of a scale of points; b) classification into categories; c) the publication of the points of the classification with a view to the professional education of the breeder; d) the use of measurements at Shows; e) the ideal type of cattle for Belgium.

a) Animals which have already been subjected to two preliminary tests should alone be admitted to examination. The first of these tests eliminates all cattle that are not entered in the Herdbook, or (in the case of cows) are not provided with a milk production certificate, and of which the body-measurements (such as height, circumference of chest), do not correspond with those of the type (to be determined according to the agricultural district); the second excludes all animals which are not of the required type; are unsuitable for breeding purposes.

es; are too fat, or show any defect in conformation that should be eliminated from the breed.

The authors advise: a jury of 3; a percentage-card with the marks: 10 perfect; 9 very good; 8, 7, 6 good; 5 tolerably good; 4 fair; 3, 2, 1 mediocre; 0 poor; the use of the simplest forms owing to the lack of uniformity in the Belgian breeds. On the strength of their personal experience they suggest the form reproduced in Table III.

TABLE III. — *Form used in Belgium.*

Judge No . . . . .		. . . . .		
Bull No . . . . .		. . . . .		
Maximum		Coefficients	Number of points	Products
			Out of 10	
40	Required type conformation capacity and weight . . . . .	4		
10	Line of back . . . . .	1		
20	Pelvis and buttocks . . . . .	2		
10	Chest (girth and flanks . . . . .	1		
20	Limbs (including shoulders, equilibrium gait . . . . .	2		
Total obtained out of 100				
To be subtracted from excess of fat (from 1-10) . . .				
Accredited total out of 100				

The form for the cows differs from that used for bulls, in as much as 10 points are added to the 3rd and 5th note, and 20 to a 6th: udder and teats.

Another model form gives a summary of the decision of the 3 judges and is the final opinion. It is not at present possible to credit cows with points for pedigree and tests of milk production. High points are given for the required type, this being necessary in the case of breeds with irregular variations.

b) In classing cattle, the number of prizes and of animals to be placed in each category should not be settled beforehand, for both should depend upon the number of good cattle entered. The total sum of the prize-money can, however, be fixed in advance, and also the number of classes and the proportion between the value of the prizes offered for each class: for instance the 1st prize may be four times, and the 2nd twice as much as the 3rd.

In order to draw attention to the type of animal desired, it is well to give one or more diplomas of honour to exceptional animals in the 1st Class.

d) The best type cannot be determined solely by means of body-measurements, which are, however, very helpful to the judges in forming an opinion of the conformation of the animals. As a model of a form based on measurements, the author reproduces the one adopted in Switzerland, where long experience has made it possible to determine fairly approximately the ideal measurements.

Age of the animal examined

[illegible]

(1) body-length 100.

As an example of model Shows that have proved the fallacy of the idea, very commonly met with among breeders, that conformation and a high milk yield are antagonistic, the authors mention those held in the Department of Seine-Intérieure (France) (1).

The author brings out the necessity for determining the ideal type of cattle for Belgium; he discusses the required characteristics which should be: good conformation, great capacity for milk and butter-production, fairly early maturity.

This type occurs more or less frequently throughout the agricultural region, but the animals differ in size and in secondary ethnical characters, hence the defects and good qualities of the cattle are determined

(1) See R. Dec. 1921, No. 1256. (Ed.)

by regions, the average measurements of the animals being compared with those of the standard type.

It is thus possible to compare the measurements of the cattle of the different agricultural regions, and by this means, to deduce their characters, as has already been done for Flanders by Prof. ZWAENEPOEL, *Annales de Médecine vétérinaire*, 1914. In this way, the authors have discovered that the Condroz cattle have a longer croup than the Herve cattle.

When the best average weight of an adult animal in good condition has been determined for a given region, the most economically satisfactory chest circumference to be taken as a type is that expressed by CREVAT's formula :  $P = 80 C^3$ , where P is the weight and C the circumference of the chest.

VI. — JUDGING COWS FOR MILK AND BUTTER PRODUCTION. — In October 1920, the Municipality of Lisieux (Department of Calvados, Normandy), opened a competition for milch cows. The first day the competing animals (46) were examined as regards their conformation by 3 judges who used percentage forms; in the evening, the cows were thoroughly milked; the next day the milk from each of the 3 milkings of the day was weighed and analysed according to GERBER's method.

COLOMBE compares and discusses the results thus obtained and shows that there is not sufficient parallelism between the number of points accredited to the cows and their actual milk and butter yields. On the whole, however, the highest points were given to cows which gave the largest amounts of milk on the following day, and no poor milker was scored high, or *vice versa*; the same cannot however be said for the butter production.

These results prove that no conclusion as to butter-producing capacity can be obtained from external appearance or empirical characters.

The author therefore proposes that the examination of cows at shows should be divided into two different parts, and entrusted to two sets of judges, the first part consisting of an examination of the general conformation of the animal, the results being entered on a simple form, whereas in the second, the characters of production which it is desired to improve should be considered and expressed by points multiplied by a coefficient and entered on the preceding form in order that they may be included in the total number of points awarded. F. D.

456 - **Wintering and Summer Fattening of Cattle in North Carolina, United States.** — FARLEY, F. W., and PEDEN, P. T. (Animal Husbandry Division, Bureau of Animal Industry) and CURTIS, R. S. (North Carolina Experiment Station), in *United States Department of Agriculture, Bulletin No. 954*, 18 plates, figs. 5. Washington 1921.

In the autumn of 1913, the Bureau of Animal Industry of the Department of Agriculture of the United States, in collaboration with the Agricultural Experiment Station of North Carolina, began a series of experiments in feeding beef cattle in the county of Haywood (North Carolina), which is the western part of the State and where most of the cattle reared are destined for beef production.

The work lasted for 6 years, and the results of the experiments of the first 3 years have already been published (1); those of the 3 last years form the subject of the Bulletin analysed.

In each group of experiments there were 17 to 40 calves of over a year old. The average duration of the winter feeding was 126 days beginning from December 12; the period of summer grazing lasted on an average 140 days. The lots fed mixed hay throughout the winter received on an average during the 3 years, 5 kg. of hay per head and per day; they lost 22.7 kg. of live-weight during wintering and gained 130 kg. during the whole course of the experiment, viz, in 266 days.

The lots fed all the winter on the ration of 12.25 kg. of maize silage per head and per day lost 18 kg. of live weight during the winter, and gained 134 kg. during the whole period of the experiment.

The lots that were fed throughout the winter on maize silage + maize stover + hay, consumed 6.9 kg. of the maize silage + and 2.8 kg. of the maize stalks and hay per head and per day. They lost 35 kg. of their weight during the winter, but increased 119 kg. in the whole period of the experiment.

The lots that grazed during the winter on detorested land and received a little mixed hay or maize stalks and straw during the short time the ground was covered with snow, lost 13 kg. of weight during the winter and gained 138 kg. during the whole experiment.

The lot fed all the winter (for one year only), on maize stalks + hay + straw, consumed 4.5 kg per head and per day during the winter; during this period they lost 29 kg of live weight and gained 128 kg. during the whole time the experiment lasted.

It was found that the cost of the food and the increase in live weight were on an average about the same, whether the cattle were fed throughout the winter on maize silage, or mixed hay. The ration maize silage + maize stalks + hay was much less expensive than mixed hay and maize silage alone. Winter grazing was the most satisfactory method of feeding, both on account of its cheapness and the increase of live weight obtained in the year. The authors also give rules for laying down meadows to be used as winter pasture.

The general average cost of feeding for the 4 winter months was about half the feeding cost for the whole year.

The mean cost per quintal of increase in live weight in the case of all the animals used in the experiment was 30 % higher in spring than in autumn. In the spring, the average loss of live weight was 6.5 %, calculating from their weight in the preceding autumn.

457 - **Sheep-Breeding in Syria and Cilicia.** *Haut Commissariat de la République française en Syrie et au Liban. Notes sur l'élevage du mouton en Syrie et en Cilicie*, 55 pp., 3 appendices. Beyrouth, November 1921.

These notes have been compiled by E. ACHARD, Head of the Agricultural service of the High Commissariat from information collected by

(1) In *Bulletin* No. 628, U. S. Department of Agriculture, summarised in *R* Feb 1919, No. 227. (Ed)

himself and from documentary evidence supplied by General MARTY for Cilicia, PAVIE and DJERRAHIAN for the Government of Aleppo, Com<sup>t</sup> Le BOULANGER, Com<sup>t</sup> DEVAUX, and H. RAMIZ MAKHZUMI for the Government of Damascus, Capt. MIEG, BRAIDY, ARSLAN, and NOUR for the Government of Great Lebanon, Col. NIEGER for the Territory of the Alaouites, CAYLA for the Sandjak of Alexandrette, and DUMONT the Chef d'escadrons for the sandjak of Djebel Bereket.

Syrian livestock consists chiefly of sheep, goats although much fewer in number coming next.

Syrian sheep belong to different varieties of the Asiatic breed (*Ovis aries asiatica*). They have the characteristic masses of fat on either side of the tail (fat-tailed sheep).

In some regions e. g. Turkestan, these masses of fat attain the weight of 16 kg. In Syria however they never appear to exceed 6 kg.

These accumulations of fat, which are no doubt a reserve stock, may disappear if the animals are reared for several generations on fertile land e. g. the civirdjik variety in Anatolia and the arab in Algeria.

The fleeces of the lambs of certain breeds supply a fur comparable to Astrakan (Karacul)

VARIETIES. — The most widely distributed variety is the "awass" which is the name of a nomad tribe of the Euphrates by which it is bred. These sheep are met with in Mesopotamia, Syria and Lebanon, where they are kept by the nomads. There are two sub-varieties: the "awass baladi" and the "awass deiry" of the region of Deir er Zor.

The height of the average "awass" sheep is 0.70 m. and its length varies from 1 m. to 1.10 m. The fleece is white though occasionally there are patches of black on the neck and head, and sometimes coffee-coloured animals are to be seen. The wool is straight and not much appreciated on the European markets; the first shearing is the best. When in yolk, the fleece weighs about 2.250 kg., but it loses 50 % in washing. The staple is from 0.15 m. to 0.18 m. in length. These sheep are good walkers, sometimes travelling as far as 400 km., they are very resistant to disease and variations of climate, but are susceptible to thirst and cannot find food in winter if the ground is covered with snow.

They fatten well (producing 30 kg. of fairly good mutton at the age of 3 years), and are good milkers.

In the Government of Aleppo are found: the "moor" variety (of Erzeroum), height 0.75 m.; the rams, unlike the ewes, have a straight forehead. The locks of the fleece which is of a dark red colour, are 0.12 m. long. The moor sheep produces from 30 to 35 kg. of mutton. It suffers from the heat in Syria for it cannot be said to be properly acclimatised.

The "brezi" variety bred by the Kurds, 0.70 m. in height; forehead straight, fleece white, wool straight.

In the Horns-Hanca region are found:

The different "awass" varieties. The *awass deiry* type, called "tchfalich" in Lebanon, and "djefeyli" in Cilicia, is 0.60 m. in height,

0.80 m. in length and has no horns. Its wool is little valued and opinions as to the merits of this sheep differ in the various regions.

The "*hamra*" variety, native of Kurdistan, with red fleece.

The "*avijé*" variety.

The "*brasieh*" variety, tall, hornless, white. The "*tchoum*" and "*carha*" varieties.

In the territory of Great Lebanon, there are: the two types of the "*awass*" variety which seems to have improved somewhat as a result of better feeding.

The "*herrick deraa*" variety which is apparently the "*dziziré*" of Cilicia. Tall, fleece white, hairy parts thick, head and neck black, hornless, mutton of average quality, shows little resistance to disease.

The "*kerbalich-hamra*" variety is distinguished by its height, chestnut fleece and hairless tail; it would appear to be the same as the "*bach-kalé*" of Cilicia and is regarded as one of the finest breeds.

The "*tchafalich*" and "*moor*" varieties.

In Hauran, the "*awass*" variety alone is kept. In the territory of the Alaouites, 50 % of the sheep belong to the "*fallahi*" breed (which is considered indigenous); the animals are small, weighing 45 kg. (when dressed, the yield is 50 %), 40 % belong to the "*awass*" breed and the rest represent different varieties.

The "*moor*" sheep is predominant in the Alexandrette "sandjak", its fleece is often white. This variety fattens well, yielding 50 to 60 % when dressed and it is very resistant. In the sandjak of Djebel Bereket, are found (in order of merit), the "*melemendji*", "*caramanli*" and "*ain-dinli*" breeds the 2 latter are also predominant in Cilicia.

**SHEEP-BREEDING.** — Sheep are reared both by the stationary and the nomadic tribes, the latter possessing the greater number of animals. The flocks raised by the stationary tribes live throughout the year on fallow-land or stubble fields or else travel, according to the pasturage that is available in the district.

Sheep-breeding is not making progress and in certain districts it may even be said to be losing ground owing to the great decrease in the flocks (amounting to 80 % in the region of Alexandrette), which were used for provisioning the Turkish and German troops during the military operations in the country. Any increase in the number of sheep is checked by the scarcity of summer watering places; in autumn and winter the animals are in such a weak condition that they are easily affected by unfavourable conditions of weather. Immense tracts could be utilised for sheep-breeding if the example of South Algeria were followed and numerous watering places made for the flocks. In this way, certain districts might be turned to good account, which at present owing to the shortage of agricultural labour are unlikely to be cultivated for many years.

Epizootic disease is also partly responsible for hindering the development of sheep-breeding; although in the case of stationary flocks, it should be relatively easy for the veterinary service to establish adequate control,

while by restricting the wanderings of the travelling flocks to certain districts, all danger of thus spreading infection could be avoided.

The sheep-breeding industry is well worth development in Syria, for the climate allows the animals to remain in the open throughout the year, while the different products of the flock can command a good market.

**SHEEP-BREEDING CONDITIONS.** — The animals are either reared by the owner himself who pays a shepherd, or else by several associated owners who entrust their animals to a shepherd with whom they share the profits on an agreed scale. The former method is employed chiefly among the stationary breeders.

The author describes the different forms of contract which vary according to district.

Co-operative breeding is fairly common in the Governments of Damascus and Aleppo, especially among the large landowners in the rural districts. The terms of the agreement vary considerably in different places and all forms are described in detail.

**BREEDING.** — As a rule, rams and ewes are used for breeding when 2 years of age, but this takes place earlier or later according to the district.

Animals are rejected for breeding purposes when they are about 5 years old though in some parts of the country, the age is fixed at 3 years, while in others it is extended to 7 or even 12 years e g in the territories of the Alaouites

Rams are as a rule allowed to run with the ewes throughout the year, although in some districts they are kept apart from August to September. Mating begins in July and is sometimes continued until September 15. The number of ewes served by one ram varies considerably in Lebanon, 15 rams are provided for 100 ewes, while in Cilicia (where it is said hand service is sometimes practised) a single ram is put to from 80 to 100 ewes.

Most of the ewes give birth to one lamb, twins being rare and triplets still more unusual. It is reckoned that 5-8 % of the sheep produce twins.

The mortality among the lambs varies with the climatic conditions, but never exceeds 5 to 10 %, and in average seasons the growth of the flock is estimated at from 50 to 60 %. Lambs are separated from their dams a few days after birth, and may then only be suckled twice or thrice a day and are at grass the rest of the time.

**CASTRATION.** — In Hauran and amongst the Alaouites, the young rams are not castrated, but if not required for breeding purposes, are sent at an early age to the butcher.

In Lebanon the operation is effected when the animals are 18 months old, and in Cilicia between the second and fourth month. In the district of Hama lambs are not castrated until they are a year old, as the Arabs consider that the operation stops growth. The usual method adopted is twisting the seminal cord, although in some regions the testicles are removed or crushed. The losses due to castration are computed at 1-3 %.

**IMPROVEMENT OF THE FLOCK.** — Selection and crossing are only carried out on a very small scale and unscientifically. As a rule, breeders aim chiefly at producing a tall animal, but whether this preference is governed by the desire of obtaining good walkers or larger fleeces is not very clear.

**PASTURAGE.** — The home keeping sheep-breeders send their sheep to graze on the fallow-land and stubble fields near the villages while the nomads let their flocks feed in the desert during the winter and spring, and in summer invade the districts occupied by the stationary population, where they are welcomed, as their sheep are supposed to manure the land. In some districts a payment varying in amount is made to the land-owner.

In Syria, besides the mountainous districts, there are regions with meadows that are either perennial or can be pastured for the greater part of the year, e. g. the plain of Amk, lower valley of the Karasu, Harini, Gharb; the plains of Akkar, and Bekaa, the banks of the Euphrates, the pastures of Harash etc.

**SEASONAL AND GENERAL MIGRATION.** — Seasonal migration is rarely followed, for most of the sheep-breeding is in the hands of the nomads; it is, however, practised in some parts of Great Lebanon and is very common in Cilicia where the flocks leave the plains in April and do not return until October. In the sandjak of Djebel-Berket, there are nomad tribes that pass the winter in the plain and spend the summer in the hills.

The author gives a detailed account of the migration of the flocks and describes the manners and customs of the nomad tribes as well as their summer and winter camping grounds. Many of these natives breed camels as well as sheep.

**LACTATION.** — The lactation period varies from 4 to 5 months; the average milk production during the time being 500 gm., this low yield being probably due to irregularity in reeding. The sheep are generally milked once a day; the milk is rich in cream. Except in Cilicia, the milk is consumed by the family, much coagulated milk (yoghourt), butter and cheese being made. In any case, most of the products are used locally.

**SHEARING.** — Shearing begins on March 15 (Cilicia, Aleppo), and is generally continued through April, finishing in May in the upland districts. Owing to the mildness of the climate, the sheep are completely shorn. The animals are not washed before shearing and the weight of the fleeces in yolk varies between 500 gm. (Cilicia), and 2.5 kg. (Hama). The value of the wool varies with the different breeds.

**DISEASES AND PARASITES.** — The diseases that have been identified in Syria are: bacterial anthrax, known as "thal" in Homs-Hama, "tehhaïel" in Hauran, "pohal" in Lebanon, and "hamra" among the Alaouites.

Symptomatic anthrax sometimes occurs. No serious attempts at treatment are made.

Foot-and-mouth disease, called "tibae"; the infected animals are isolated and their hoofs covered with tar or carbolic acid;

Scab, called "djedri"; this disease sometimes attacks 50 % of the flocks.

Verminous bronchitis, known as "dondel el chaar"; distomatosis, called in Arabic "tbou donedar"; "mirara" which appears to be piroplasmosis;

Sarcoptic and psoroptic mange ("djarabe"); the diseased animal is shorn without cutting the skin, washed in soapy water and covered with an ointment consisting of equal parts of tar, sulphur and oil;

The fever called "errojet" is apparently due to flatulence;

Foot-rot which is treated with tar, sulphate of iron baths and various herbs.

Pasteurellosis, contagious pneumonia, jaundice and fleas. Other diseases are rife but cannot be accurately diagnosed.

TRADE IN SHEEP AND THEIR PRODUCTS. — There are three chief branches of trade.

- 1) Importation from the neighbouring region;
- 2) Exportation to the Islands of the Archipelago and Egypt,
- 3) Transactions connected with the local flock

Most of the imported sheep come from Mesopotamia, but this trade has considerably decreased since the War. The animals are sent overland to their destination and details are given of the different routes.

Exportation is very limited and chiefly confined to Egypt and the Islands of the Archipelago.

Most of the meat consumed in Syria and Cilicia is mutton and goat's flesh. At Beyrout the number of sheep, lambs and goats slaughtered in 1920-21 was 69 000. At Aleppo the total number slaughtered was 210 000, of which 100 000 were lambs.

In Lebanon, sheep are fattened for home consumption. In 2 or 3 months the animals weigh from 60 to 80 kg. Their flesh is made into "kawarma", a mixture of fat and meat used as provisions for the winter.

The wool loses at least 50 % of its weight on washing. The fleeces of the animals sent to the butchers' are also put on the market, but fetch 20 % less than shorn wool.

When the wool has been washed and sorted, it is packed for export. The wools of Syria are classed under the heads of.

White, grey, black fleeces.

White, grey, black pelts

Yellow "clips"

The latter are the ends of the fleeces and sell for 20 to 30 % less than the white pelts.

Before the War, the United States were the largest importers of Syrian wool, most of it now (50 to 55 %) goes to France.

The wool that remains in the country is used for making a kind of felt known as "libbadé" (the process of manufacture is here described), ropes, cord and sacking.

A good deal of butter used to be exported, but as exportation from Anatolia is at present impossible, all the butter made in the country of late years has been consumed locally. The much vaunted Aleppo butter is for the most part made in the adjacent districts and brought to the town to be refined. A description of the process is given.

In 1920, 1500 *kantars* of 250 kg. of butter of the value of about 5 500 000 fr. were produced in Hama. Before the War Aleppo sold annually 2 million kg. of the value of some 4 million fr. Owing to the interruption of all commerce with Anatolia this trade has now decreased 50 %.

The district of Aleppo, properly so-called, produced in 1920 the same amount of butter as in 1914, or 20 % of the product that passes under the name of Aleppo butter. The average price is at present 20 fr. per kg.

The sheep-skins are either used locally or exported. There are tanneries in Syria at Aleppo, Antioch, and Zahlé and an account is given of the methods employed.

Skins for export are only slightly salted and dried; most of them come from the abattoirs. Previous to the War, Aleppo exported 250 000 sheep-skins but the number has now fallen to 100 000.

The residuum is exported (in the form of salted intestines) to Germany and Austria, while the horns furnish material for a local industry.

Some statistical data are given in order to complete this study and it is stated that, though it is very difficult to obtain reliable figures the number of sheep may be estimated at 10 466 346. P. C.

458 - **Fertility in Shropshire Sheep, in the United States.** — ROBERTS, E., in *Journal of Agricultural Research*, Vol. XXII, No. 4, p. 231-231. Washington, October 1921.

HEAPE in 1899 made the statement that in some breeds the younger ewes bear fewer twins than the older.

CARLYLE and MAC CONNEL conclude from their observations, made in 1902, that ewes from 3 to 4 years old produced a larger percentage of lambs than younger or older ewes and also that 1-year-old rams were less prolific than 2 or 3 year old rams. The same conclusions were reached by HUMPHREY and KLEINHEINZ from a study of the records of the Wisconsin flock. JONES and ROUSE reported in 1920 that in the case of sheep the percentage of twins increased with age up to 5 years, after which there was a marked decrease.

The author has studied the influence of age and season upon fertility in the American Shropshire sheep. His source of data is the American Shropshire Sheep Record in which he examined 19 367 entries.

**AGE OF EWE AND FERTILITY.** — The percentage of multiple births increases with age up to 4 years and remains fairly constant for 8 years.

**THE AGE OF THE RAM AND FERTILITY.** — The age of the ram has no influence on the percentage of multiple births.

**TIME OF BIRTH AND TWINNING.** — HEAPE, who collected information from flock masters, states that 55 % of them reported that twins were usually born early in the lambing season. The author has found that the percentages of multiple births are 43.1 from January to March, and

36.7 from April to July. In the hope that additional information might be obtained, a study was made of the Dorset breed which produces a large number of young in the autumn. It was found that the percentage of multiple births was highest in the spring, being 48.2 from February to June inclusive as against 34.9 for the other months. F. D.

459 - **Lamb-Fattening Experiments in the United States.** — I. HAMMOND, J. W., Green Forage Crops and Corn for Fattening Lambs, in *Bulletin of the Ohio Agricultural Experiment Station*, No. 340, pp. 35-99, Tables 28, figs. 16, Wooster, Ohio, 1920. — II. PATERSON, A. M., and WINCHESTER, N. B., Lamb Feeding Investigations 1919-1920, in *Agricultural Experiment Station, Kansas State Agricultural College, Manhattan, Kansas, Circular 88*, pp. 6, fig. 1 Topeka, 1921.

I. **TEMPORARY PASTURES AND MAIZE GRAIN FOR FATTENING LAMBS.** — 1st *Experiment.* — Comparisons were made between 1) meadow-grass and colza; 2) grazing alone and grazing + maize grain; 3) grazing and stall feeding, no grass being given.

2nd *Experiment.* — In this experiment comparisons were made between 1) meadow grass, and rye, clover, and rape which were grazed successively; 2) grazing alone and grazing + maize; 3) grazing and stall feeding. In addition, the effect of the ration upon parasitic infestation was also studied.

3rd *Experiment.* — The three comparisons made in the 2nd experiment were repeated and the development of pure Merino lambs compared with that of hybrid Shropshire × Merino lambs.

4th *Experiment.* — Comparisons were made between the different rations of maize given as a supplement to grazing on rape, and the comparison between the Merino and the Shropshire × Merino lambs was again repeated.

The experiments were carried out on the South-Eastern Test Farm at Carpenter, Ohio. The fields of meadow-grass, owing to the character of the soil, were not of the best quality.

In Experiment I the average initial live-weight of the lambs was about 241 lb.; they were kept on grass for 131 days dating from June 14. The average daily increase in live-weight for the lot kept on meadow grass was 0.11 lb. per head, while that for the lot kept on rape was 0.113 lb.; the increase per hectare was, however, 48 lb. and 214 lb. respectively.

In experiments 2 and 3 the average initial live weight of the lambs was about 33 lb. In the 2nd experiment, the average daily gain in live-weight of the lot kept on meadow-grass was 0.34 lb. during the 153 days dating from May 11, and that of the lot grazed successively on temporary fields of rye (8 days), meadow-clover (48 days), and rape (97 days) was 0.40 lb.

In experiment No. 3, the lambs grazed for 160 days dating from May 9. The average daily gain in live weight was 0.175 lb. on meadow-grass, and 0.24 lb. for the lot kept successively on rye (22 days), meadow-clover (36 days) and rape (102 days). As compared with grazing on meadow-grass (experiment 1), grazing on rape gave a higher daily increase in live weight of 2.73 % per head; grazing successively upon land under different

forage crops gave an excess increase of 19.79 % in experiment No. 2 and of 33.06 % in experiment No. 3.

In experiments 1-2-3 one acre of rape produced the same increase in live-weight as 5.04; 9.25; 8.19 acres of meadow grass respectively during the time the animals were left to graze.

In Experiment 1 the land under rape supported 403 lambs per acre for 131 days, and produced 24c lb. or increase in live-weight per acre. In experiment No. 2 it supported 22 lambs per acre for 97 days and produced an increase in live-weight of 185 lb. In experiment No. 3 there were respectively 60 Merino lambs per acre for 77 days, and an increase in live-weight of 203 lb. per acre; 97.5 Shropshire × Merino lambs per acre for 25 days and an increase in live-weight of 166 lb. per acre.

If the value of the land under rape is estimated at three or four times that of meadow-grass pasture, the cost of production per lb. of live weight is about equal.

The rape-fed lambs fattened better and sold at a higher price per kg., their yield as butcher's meat was also higher.

The results of the three experiments show that rape is an excellent forage plant for fattening lambs, especially in districts where good permanent pastures are rare. A temporary rape meadow can also often be used with advantage to supplement meadow-grass pastures during the summer when they are probably dried up, uninviting and infested by gastro-intestinal parasites left by the sheep.

As regards the effect exercised by the pasturage upon parasitic infestation, it was noted in experiment No. 2 that almost the same number of stomach-worms were present in animals turned out on to natural meadows, as in those that had grazed on temporary pasture land. The first had, however, the larger number of intestinal nodes.

The half-bred Shropshire × Merino lambs gave per acre of land under rye or meadow-clover, a larger increase in live-weight than the Merino lambs similarly fed. The results varied, as regards the animals kept on rape, sometimes in favour of the half-bred lambs, sometimes in favour of the Merinoes. The half-bred lambs reached a higher degree of final fattening.

*4th Experiment.* — This took place at the Wooster Experiment Station (Ohio) and was carried out in order: 1) to determine the economy of giving a whole or half ration of maize as a supplementary food for lambs kept on rape fields; 2) to compare Shropshire lambs with half-bred Shropshire × Merino lambs as regards the cost and character of the live-weight produced by grazing on rape and the rate at which it is obtained. For this experiment 6 lots of 10 sheep each were chosen and the animals used in the preceding experiments, Nos. 2 and 3, served as control lots for the following years. Feeding a supplementary maize ration augmented the increase in live-weight: this increase was 11.5 % the first year, and 35.5 % the next, in the case of the lots kept on the meadow-grass field; and 12.6 and 21.1 % for the lots on the fields planted with other crops;

in addition, the dressing-yield and the value per lb of live weight increased in all the cases

The experiments at Wooster were made in 1917 with improved but not pure-bred Shropshire lambs of an average initial weight of about 53 lb, and with half-bred Shropshire  $\times$  Merino lambs of an initial weight of some 46 lb. Both lots were kept on rape and divided into 3 groups receiving respectively a whole supplementary ration of maize (i.e. the whole ration that could be consumed in one morning), half a supplementary ration (what they found on the temporary pasture in the case of the control group). The average daily increase in weight per head was 4.5 oz in the case of the Shropshire, and 5.3 oz for the hybrid lambs in the control groups, as against 5.0 oz and 5.3 oz respectively in the group receiving the supplementary half ration, and 5.4 oz and 5.5 oz in the group given the whole supplementary ration. There was practically no difference in the final degree of fattening, nor in the yield at the butcher's.

It is true that the half bred lambs had a slight advantage as regards rapidity and economy in the increase in live-weight and the increase in weight per surface unit but further experiments are necessary before this superiority can be clearly established.

II LAMB FEEDING EXPERIMENTS IN IDAHO 1919 1920. The two sets of experiments described in the bulletin analysed were made for the purpose of comparing rationing with self feeding and of determining the comparative value of several concentrated feeds.

*First Experiment* — Five lots of 40 lambs with an average initial weight of about 55.7 lb were fed as follows for 64 days beginning on November 2, 1919. 4 lots were given 1.25 lb grain + 0.14 lb linseed-oil meal in addition to lucerne hay and cane silage the other lot was self-fed and consumed 1.40 lb shelled maize and 0.55 lb linseed-oil meal per head and per day. The last lot ate less bulky feeds than the hand fed lambs, made 0.03 lb greater average daily gain per lamb fattened better and gave a higher dressing percentage (50.06). Of the other lots No. 2, fed shelled maize gained daily 0.48 lb per head. No. 5 fed shelled maize and given in addition stock tonic gained 0.47 lb daily per head. Lot No. 3 fed ground maize also gained 0.47 lb daily per head while the lowest daily gain per head was made by the lambs of lot No. 4 which was fed whole barley. The dressing percentage of this lot was also the lowest. The dressing percentage for the 4 groups was respectively 49.1, 49.5, 48.8 and 48.2.

*Second Experiment* — This began on February 8, 1920, and lasted 30 days. 6 lots of 35 lambs each were used. The initial weight of each animal was about 73 lb and the final weight about 88 lb.

The self-fed lot (No. 1) were given daily per head 1.52 lb shelled maize + 0.49 lb linseed oil meal + 1.05 lb lucerne hay + 0.98 lb maize silage and made an average daily gain of 0.55 lb per lamb. The same average daily gain was made with the hand fed lambs (lot 3). The daily ration per head of the hand fed lambs was — shelled maize 1.10 lb + linseed oil

meal 0.23 lb. + 1.07 lucerne hay + 2.10 lb. maize silage. The self-fed lot ate more maize and less silage than the hand fed lot.

When linseed-oil meal was left out of the basal ration of the hand-fed lambs (Lot 6) the average daily gain per lamb was only 0.42 lb., whereas the gain of the self-fed lambs (Lot 2) given the same food was 0.54 lb., with the consumption of 1.62 lb. maize per head and per day.

The hand-fed lot (No. 3) fed linseed-oil meal made 0.01 lb. less average daily gain per lamb than those receiving 34 lb. maize gluten feed (lot 5).

Lot 4 which was only fed shelled-maize and lucerne hay made a daily gain of 0.47 lb. per head and fattened less than any of the others.

The feed required for 100 lb. gain was as follows :

Lot 1. 276.27 lb. shelled maize + 88.86 lb. linseed oil meal + 190.36 lb. lucerne hay + 177.88 lb. maize silage.

Lot 2. 301.77 lb. shelled maize + 195.27 lb. lucerne hay + 205.46 lb. maize silage.

Lot 3. 190.66 lb. shelled maize + 41.52 lb. linseed oil meal + 195.16 lb. lucerne hay + 382.27 lb. maize silage.

Lot 4. 225.66 shelled maize + 498.63 lb. lucerne hay.

Lot 5. 186.78 lb. shelled maize + 61.02 maize gluten feed + 191.70 lb. lucerne hay + 348.73 lb. maize silage.

Lot 6. 248.76 lb. shelled maize + 255.30 lb. lucerne hay + 468.85 lb. maize silage.

Fat lambs weighing from 80 to 85 lb. are in greatest demand on the market. Therefore lambs weighing around 55 lb. are the most profitable type to feed. The larger type of feeding lamb is not fat enough at 85 lb. and is too heavy to command a profitable price. F. D.

460 - **Swine-Feeding Experiments in Kansas, United States.** -- FERRIN E. F., and WINCHESTER, H. B., in *Agricultural Experiment Station, Kansas State Agricultural College, Manhattan, Kansas, Circular 80*, 10 pp. Topeka, 1921.

A COMPARISON BETWEEN BARLEY AND MAIZE AS A SUPPLEMENTARY FEED FOR PIGS ON PASTURE. — Forty pigs divided into 4 lots of 10 each, were used in this experiment which lasted 120 days, beginning from July 1, 1919.

One pig out of Lot 1 died. The average initial weight of the animals was about 37 lb. The rations fed and consumed are given in Table I.

These results show that maize grain is more satisfactory for fattening pigs than barley which is too bulky owing to the large quantity of hull. In the preparation of barley, grinding gives better results than soaking the grain, especially if the feed is to be given to young pigs.

THE COMPARATIVE FEEDING VALUE OF MAIZE AND LOW-GRADE WHEAT. — This experiment lasted 120 days beginning on September 15, 1919. Most of the pigs used had been running on lucerne pasture until the test started from which time they were fed in dry lots. Fifty pigs were secured for the experiment, and their average initial weight was about 60 lb. The rations fed and their relative efficiency are shown in Table II. It may be said that, given equal amounts larger returns are obtained from

wheat than from maize; hence if the prices are approximately equal, wheat is to be preferred to maize.

TABLE I — *Barley versus Maize for Pigs on Lucerne Pasture.*

Food	Feed required for 100 lb. gain			
	Lot 1	Lot 2	Lot 3	Lot 4
	lb	lb	lb	lb.

Ground maize	17.85	—	—	—	485.27
Tankage	—	19.30	—	—	22.23
<b>Totals</b>	<b>407.91</b>	<b>422.18</b>	<b>466.51</b>	<b>491.54</b>	<b>507.50</b>
Relative efficiency of rations	100	96.62	87.44	82.98	80.38

VALUE OF RYE AS A SUBSTITUTE FOR MAIZE — This experiment was made on 5 lots of 10 pigs with an average initial weight of about 60 lb., it lasted 120 days beginning on September 15. The results given in Table III, show that in times of high-priced maize, rye if available can probably be used to a larger extent than hitherto. Some more palatable food should however be mixed with it.

GRAIN SORGHUMS COMPARED WITH MAIZE — An experiment lasting 60 days and beginning on February 17, 1920. Two groups of pigs were used, one farrowed in the spring, and the other in the autumn. Each

group was divided into 4 lots of 5 pigs. The various lots were fed ground maize or sorghum, and tankage. The results, given in Table IV show that sorghum grains, especially milo and feterita, are nearly as good as maize for feeding pigs and may possibly be better than maize for fattening-purposes.

If sorghum is substituted for maize, more tankage is needed. The right quantity of tankage was fed in this experiment, viz., 3.7 % of the total feed consumed in the case of 150-pound pigs and 4.7 % in that of 100 lb. pigs.

TABLE IV. — *Effect of the Age of the Pigs upon the Amount of Feeds required for One lb. Gain in Live Weight.*

461 - Concentrated Pig Foods. Experiments made in France. — DE MARSAY, Vte H., and BAUDOUY, in *Journal d'Agriculture pratique*, Year 85, Vol. II, No. 45, p. 396, Paris, November 12, 1921; year 86, Vol. I, No. 6, p. 122. February 11, 1922.

I. — From September 14 a lot of 14 pigs weighing 1067 kg. were given as much as they could eat for 20 days, during which time they gained in

weight 218 kg representing a pecuniary gain of 4 30 fr (cost of 1 kg. of live-weight)  $\times 218 = 937$  40 fr The cost of the food was as follows:

420 kg manioc meal at 0 66 fr the kg	277 20
240 kg barley meal at 0 70 fr the kg	168 00
100 kg pea nut meal at 0 56 fr the kg	56 00
700 litres whey at 0 05 fr the litre	35 00

536 20

Gross profit 93 40 fr — 536 20 fr = 4 120 fr

Grain per pig and per day 401 20 fr. 2.80 — 1 44 fr

II — 85 rationed pigs given 3 to 4 kg whey + 1 kg manioc + 1 kg barley + 0 5 kg pea-nuts, or a ration costing about 2 francs, also gave a good return with meat at the present price

III — A hundred pigs were fed the following ration 500 gm maize + 500 gm sorghum + 1000 gm palm-oil cake + 500 gm pea-nuts + 200 gm. bone-meal + several litres of whey, distributed as follows palm-oil cake, pea-nuts, bone meal crushed sorghum mixed with whey and given warm in the morning the same ration in the evening maize grain at midday Sorghum fed whole is not digested well but is very digestible when either ground or crushed

After 30 days the following results had been obtained

Daily gain of unrationed pig fed maize (consumption 1 300 kg)	120 kg
Daily gain of rationed pig fed maize ( 500 kg)	0 668 "
Cost of feed of unrationed pig	2 80 fr
Cost of ration of hand fed pig	1 52 "
Daily profit of unrationed pig at 4 fr per kg of live weight)	1 308 "
Daily profit of hand fed pig	1 152 "
Difference to the advantage of unrationed pig	1 156 "

In all these experiments the cheapest concentrates obtainable were fed

From the results the following conclusions may be drawn

1) Nothing is gained by rationing pigs it is much better, to give them food *ad lib* 2) At the present time it pays very well to feed pigs on judiciously chosen concentrates

F D

## BEEKEEPING

462 — **Apiculture in Cuba and the Purity of Cuban Honey.** — (Communication made to the Permanent Committee of the International Institute of Agriculture by Dr F I FALCO, Delegate of the Republic of Cuba)

Bee-keeping is very popular in Cuba, and recently on the initiative of the Reorganisation Commission of the National Agricultural Services of the Republic, a great deal has been done to develop in every way this branch of rural economy and to stimulate actively the improvement of the breeds

The flora of Cuba is the richest and most varied in the botanical region of the Antilles and includes a large number of native species, as well as of species imported both from temperate and hot countries; it is therefore able to supply the bees with materials of excellent quality for honey-making It is reckoned that there are over 50 species of hon-

ey-bearing plants in the island ; of these some of the most important are *Aguinaldo blanco de Pascuas* (*Ipomoea sidaefolia* Choisy), which opens its flowers at dawn and closes them at three o'clock in the afternoon, and *Aguinaldo rosado* (*Ipomoea triloba* Lin.), from which the bees make the *aguinaldo* honey which has a reputation for the most delicate and delicious flavour.

The State Agricultural Experiment Station has instituted a model apiary that has of late been much developed, and has introduced selected queens of Italian stock, in order to obtain queen-bees of first rate quality for distribution to bee-keepers who wish to improve their stock of the Caucasian, Carniola, and Cyprus breeds, for in this way very satisfactory results have been obtained. The Entomological Department attached to this Station has also created a Service for the protection of bees against their natural parasitic enemies, the insects belonging to the family of the *Galleriidae* (*Galleria mellonella* and *Achroea grisella*).

Apiculture is continually on the increase and is the source of a large export trade of Cuban honey which until quite lately was much appreciated in other countries.

Recently the purity of this Cuban product has been called in question in some European countries, and this has been the occasion of a very careful investigation on the part of the interested Official Authorities of the Republic. The results of this investigation are here set out for the information of the International Institute of Agriculture by the delegate of the Cuban Republic.

Since the analyses of the honeys from Cuba had led to different conclusions, some of the honeys being regarded in many countries as of undoubted purity, while in others, importation is being checked owing to the alleged presence of invert sugars as revealed by the furfural reaction, the Laboratory of Agricultural Chemistry of the Republic resolved to make a thorough investigation of samples of known genuineness and purity, in order to be able to determine conclusively the percentage composition and qualitative characters of the chemically inverted sugar and artificial glucose probably used in the adulteration of the honey. The system followed was with slight variations that adopted by the Bureau of Chemistry of the Department of Agriculture of the United States, the object being to discover some explanation of the different treatment given to Cuban honeys by the Custom-House Officials of certain countries.

This investigation revealed that the difference was the result of analysis according to two different systems. In fact when FIEBE's hydrochloric resorcin method was adopted, the furfural colour reaction was obtained owing to the presence in almost all genuine Cuban honey of a substance, which by its special chemical action affects the reagent whereas no reaction takes place at all with BROWNE's anilin acetate method.

The first phenomenon is explained by the fact, that as many of the apiaries are situated near the sugar factories in Cuba, large quantities of saccharose are frequently within reach of the bees. They collect the saccharose on their feet and deposit it on the comb, as has been found by

analysis carried out according to the FIEHE process. Saccharose has also been detected in the honey from apiaries near the factories, although it is not found in the product of those at a greater distance, as for instance in the honey from the Isla de Pinos. Thus the presence of this sugar must be regarded as a natural characteristic of the product. Further saccharose only occurred in very small quantities in the cases quoted, the amount never exceeding 0.25 per 1000.

The report prepared from the results of the investigations at the Laboratory of Agricultural Chemistry sets forth very graphically the data obtained, and shows that FIEHE's method for the detection of adulteration of honey gives misleading results in the case of the Cuban products, and that the experiments carried out at the State laboratories of Cuba and of the United States alike have proved to demonstration the necessity for adopting the BROWNE process.

The Head of the Department of Chemistry of the Ministry of Agriculture of the Republic as a result of analyses made in the laboratories under his control, and of similar investigations made by the United States Bureau of Chemistry of the Department of Agriculture, and also taking into account the genuine nature of the samples analysed, has formulated the following conclusions.

*First* : Cuban honeys have a homogeneous chemical composition varying within very narrow limits and differing very little from the composition of honey from other countries.

*Second* : By far the greater part of Cuban honeys have the property of producing with hydrochloric resorcin a colour reaction that gives the erroneous impression that these honeys which have been recognised as pure, have been adulterated with chemically obtained invert sugars.

*Third* : In the light of these facts FIEHE's method should not be employed in the analysis of honeys made by Cuban bees.

*Fourth* : BROWNE's anilin acetate method should be exclusively recommended as the only sure test for Cuban honeys suspected of adulteration with invert sugars.

463 - Treatment of "Acarine Disease" (Isle of Wight Disease), of Bees. (1). — ALLEN W., in *British Bee Journal*, Vol. XI, IX, No. 2040, pp. 344-345. London, July 28, 1921.

In his experiments in controlling Isle of Wight disease the author has found the fumes of ammonium sulphide to be most efficacious and quite innocuous to the bees. A pad of cotton-wool dipped in ammonium sulphide is introduced between the diaphragm and the wall of the hive, which is covered to prevent the escape of the fumes. Two days after treatment all the symptoms of the disease have disappeared.

(1) See R. July 1921, No. 748. Dr. RENNIE and his collaborators have stated that Isle of Wight Disease differs from the disease caused by *Nosema aphs*. The agent is a mite *Tarsonemus woodi*, which invades the tracheal system of the bee. Dr. RENNIE suggests for this malady the name of acarine disease. (Ed.)

Allyle sulphide is equally efficacious, but is much more pungent, and very dear, whereas ammonium sulphide is cheap and easily procured.

- 464 - **The Present Condition of Sericulture in Syria.** CROIZAT, in *Revue de Botanique appliquée et d'Agriculture coloniale*, Year II, Bull No 5, pp 28-29 Paris, January 30, 1922

SERICULTURE

According to a report by the author published by the Lyons Chamber of Commerce, the output of cocoons in Syria previous to 1914 was about 4 500 000 kg 3 700 000 being produced in Lebanon and the Plain of Beha, and 800 000 in the district of Antioch. These cocoons furnished 300 000 kg. of silk, most of a very fine quality, which was destined for the French market. The mulberry was cultivated everywhere on a large scale. The silkworm eggs were brought from France in refrigerators which made it possible to obtain fairly good products, although all modern method of silkworm breeding were totally unknown in Syria.

After the War broke out, no more silkworm eggs arrived, the native "seed" produced worthless stock and finally the mulberry trees were dug up in order that food crops might be planted in their place. As a result there was a great reduction in the number of cocoons obtained which in 1919 was only  $\frac{1}{4}$  of the pre-War total in Lebanon although the importation of "seed" had been resumed, and had fallen to  $\frac{1}{8}$  in the district of Antioch where native "seed" was still used.

G. A. B.

- 465 **Observations and Researches on the Causes of the Persistence and Diffusion of Pebrine in Italy, notwithstanding the Selection of the Silk-Worm Eggs.** - MONTANARO N. (Istituto Ricerche, Portici) in *Informazioni seriche* Vol IX, No 3, pp 34-39. Rome February 5, 1922.

Although from the industrial point of view it may be said that pebrine has been conquered (for the silkworm breeder is always sure of being able to obtain healthy eggs and he is not concerned whether the cocoons he obtains contain healthy chrysalids), the disease is still very wide-spread, and it frequently happens that all or most of the moths reared from sound "seed" contain the characteristic spores.

This can be explained by 4 hypotheses:

- 1) The selection methods do not give results sufficiently perfect to eliminate entirely, infected eggs.
- 2) Breeding from infected eggs, though forbidden by law still takes place.
- 3) The germs of the parasite possess greater powers of resistance to external surroundings than has hitherto been commonly supposed.
- 4) The disease may attack other insects and therefore persist independently of the silkworm.

The author has tested experimentally the truth of the 4 hypotheses especially the first, and his results may be summarised as follows:

- 1) Of all the methods proposed for the elimination of infected moths, PASTEUR's is still the best. The negative importance of the male

in the transmission of the disease has once more been proved, for though in some experiments the malady was conveyed by the male insect, these cases were exceptional. Sound progeny can be obtained from *slightly* infected females. Thus the first hypothesis may practically be discarded.

2) One of the chief causes of the persistence of pebrine lies in breeding from uncontrolled "seed", or seed purchased from travelling dealers, or from abroad; frequently also eggs bred by the peasants are mixed with those bought.

3) The results of PASTEUR'S experiments, although not always uniform, were sufficiently general to justify the conclusion that pebrine germs lose their infectious character after drying in the air. Several other experiments have shown, however, that they are endowed with considerable powers of resistance. HUTCHINSON found that the spores continued to live in a dry medium for over 5 months and therefore their life in a damp medium would probably have been longer. The author's experiments, which are not yet finished, confirm HUTCHINSON'S statements. It is quite possible that other insects beside the silkworm harbour the pebrine parasite, in fact *Nosema bombycis* infects other Lepidoptera, such as *Gastrophaca neustria*, *Arctia caja*, *Attacus* (*Saturnia*) *pernyi*.

466 — The Use of Low Temperatures to destroy *Bombyx* Chrysalids. — DI TOCCO R., in *Informazioni seriche*, Vol IX, No 4, p. 57. Rome, February, 20, 1922.

As some silk-worm rearers have suggested the use of low temperatures for destroying the chrysalids of *Bombyx*, the author takes occasion to advise that none of the expensive apparatus required should be installed for the present, as with low temperatures the natural moisture of the cocoons cannot be absorbed as it is by storing, and the treatment is a lengthy one owing to the great summer heat, the high temperature induced by heaping up the cocoons, and the bad conductivity of the outer silk. The chief objection is however the uncertainty of the process.

Although silkworms themselves die at 8-10° C below 0° C, (SPALLANZANI), their eggs can resist, for a short time, much lower temperatures (BONAFOUS, FRIZZONI, QUAJAT), and the chrysalids take no harm, even when exposed for successive generations to temperatures below -12° C. This fact has been proved by the experiments of Prof. COLASSANTI (briefly described by the writer) of which an account was published as long ago as 1879 in the *Rendiconti dell'Accademia medica di Roma*.

F. D.

## FARM ENGINEERING.

AGRICULTURAL  
MACHINERY  
AND  
IMPLEMENTS

467 — Tractor or Motor-Plough? — SCHEMPF, in *Deutsche Landw. Presse*, No. 53, pp. 400-401. Berlin, July 6, 1921.

The author makes a comparison between tractors with motor-ploughs after a consideration of the results of the tests at Zuffenhausen (Stuttgart).

In ploughing heavy land to a depth of 20-22 cm. the tractor appear-

ed to be slightly superior to the motorplough. The furrow turned by the towed plough was better finished than the furrow made by the mould-boards of the motor-plough. The tractor also seemed easier to drive.

A 2nd test was made on very heavy, uneven land, where the tractor proved itself clearly superior to the motor plough, whose work was continually interrupted by hillocks between the mould-boards.

In the case of skidding, it was found that the wheels of the motor-plough when reversed were quite as liable to slip. With a tractor the difficulty can be better got over by the use of a chain or cable.

The results from the point of view of fuel consumption are not yet known. G. B.

468 - **One-Wheel Tractor, L' Hermite System.** — WEISS E., in *Le Génie Civil*, Vol. LXXX, No. 6, pp. 133-134. Paris, February 1922.

An agricultural tractor should be able to turn on the field like a single-horse; it ought therefore to be as easy to drive as a horse-drawn vehicle.

L'HERMITE has followed these principles in the construction of his new model tractor. This tractor has one large driving-wheel only which can turn on the field; the motor engine forms with this wheel and the accessories, a complete machine that can be pivoted on a horizontal circular attachment. This attachment carries the connections for the machines, just as a horse's harness is provided with the means of linking up with the vehicle.

The only other movable part is the central driving-wheel; hence the strength of the tractor, and the suppression of the speed-gear. The gear-case is placed in the nave of the driving-wheel.

The engine is valveless, has 2 horizontal cylinders and the distribution is very simple. A hollow cylinder communicates in the centre with the carburettor; at each extremity, it has an oblique partition which during rotation, puts the pipes supplying the cylinder in communication both with the centre of the tube for the aspiration of the carburetted mixture, and with the exhaust. To compensate for side slip a trailing wheel of small diameter is added.

The cooler consists of small vertical tubes and detachable circulating linings that are easily replaced.

Attached to the frame are horizontal rollers supporting large horizontal circular attachment which entirely surrounds the engine as the harness envelops a horse; thus the driving-wheel can at once revolve *in situ* within it. Changes of direction can be effected as quickly as in the case of a horse, and the machine can go in either direction. The steering apparatus is of a simple character and the forward and backward movement as well as the speed control are regulated by a lever.

The tractor can turn within a radius of 1 m., and can be used with a two-way plough. The tractor is placed between the two series of shares, the frames of which are arranged symmetrically to the axis of the tractor which is also the axis of turning.

The driving wheel works parallel to the direction of the plough and change of direction is made after the reversal of the shares. A supporting-wheel is placed behind each plough to regulate the depth of ploughing. In short this tractor has been specially designed for agricultural work.

One wheeled Tractor L'HERMITE.

P. C.

469 - "Massimo" Tractor, for Ploughing on Slopes. — CASTELLI M, in *La Macchina nell' Agricoltura*, Year II, No 1 pp 6-8, figs 5, Milan, January 1922

This tractor has 4 wheels, 2 driving-wheels at the back; 2 steering-wheels in front; motor-car type; runs on petrol, develops 25 H P.; rigid suspension; all transmissions by means of gearing; weighs 2600 kg. when

ready for work. This tractor is especially adapted for ploughing in hilly i. e., on uneven ground with steep slopes up to 3/10: the steering mechanism oscillates with parallel movement; the back wheels are small with a vertical displacement; transmission to the back wheels is effected by pinions engaging with an internal cog wheel attached to the wheel-body, the whole being enclosed and running in grease; reversible action; simple method of attachment.

Several experiments have been made with this tractor, and the results obtained were perfectly satisfactory. F. D.

470 - **The Heavy-Oil Engine for Agricultural Purposes.** — MÜLLER B., in *Deutsche Landw. Presse*, No. 59, p. 439. Berlin, July 27, 1921.

The author demonstrates the advantages of this type of engine from the points of view of safety, easy handling and small cost of motor-power. Practical experiments have shown that it consumes 220 gm. only of heavy oil per horse-hour. This fuel is much less expensive than petrol or paraffin. G. B.

471 - **Means of Attachment for Tractors to Farm Vehicles.** — *Deutsche Landw. Presse*, No. 45, pp. 342-343. Berlin, June 8, 1921.

The object of this apparatus is to enable ordinary farm-carts to be drawn by a tractor. After removing the pole, a bar connected by means of rods with the forecarriage is fixed on the front; in this manner, all the strain is transferred to the fore carriage. G. B.

472 - **Windlass for Cable Ploughing which Automatically changes its Position in Two Directions.** — CASTELLI M., in *L'Italia Agricola*, Year 58, No. 10, pp. 305-309. Piacenza, October 15, 1921.

The author, who has invented the apparatus described in this article, proposes to use it for the intensive cultivation of flat and hilly country for which the present large cable-drawn tractors are unsuited. As compared with such tractors, this windlass provides the necessary traction force, at about half the cost for installation. It may be called a single engine funicular apparatus whose working is eased as no ploughing is done on the return journey (which is made twice as quickly as the outward journey, during which the actual ploughing is done), and by a considerable reduction in the length of the furrows.

The windlass-cart carries the engine which is preferably driven by electricity, the transmissions and 2 drums upon which are wound the working and the return cables; these move together and their movement is transmissible also to the chief trailing-wheels whose axis is parallel to the axis of the drum. If the engine is driven by electric power, the movement is only used in the field. In order to anchor the windlass-cart, a traverse or skid is lowered carrying nearly all the weight. Any longitudinal movement in the direction of the furrows is thus prevented, whereas transverse changes of position are rendered possible by the sliding of the skid over the ground. On the opposite headland is anchored a light return pulley which is easily moved by hand during ploughing.

An ordinary plough is used ; to this can be attached a roller with a guiding-lever which facilitates its return when empty. An automatic self-raising plough of the type used for tractors, but with some slight modifications can be employed. The plough when working is drawn directly towards the windlass, that is to say without any return or deviation of the rope which is therefore not liable to become worn.

As soon as the plough has reached the windlass, the driver reverses the movement of the drums and the plough at once begins to return ; at the same moment, by the action of a small windlass also controlled by the engine, the patten supporting the windlass-cart slides along the headland changing its position by as much as the width of one or more furrows.

F. D.

- 473 - **Plough for the Rudolf Sack Tractor.** — *Deutsche Landw Presse*, No 55, p 413. Berlin, July 13, 1921

This plough is made with 3 and with 2 mould-boards worked in the first case with a rope, and in the second with a lever. The ploughing apparatus consists of an excentric that controls the nave of the land-wheel by means of a chain attachment.

G. B

- 474 - **Notes on Implements for Motor-Ploughing.** — STENDJ, in *Deutsche Landw. Presse*, No 43, p 327 Berlin, June 1, 1921

The author gives some information regarding the different W. D. implements and their use

The W. D motor-plough is provided with a 80 HP. engine and carries 5 mould-boards, a second type has an engine developing 35 HP. and is fitted with 3 mould-boards. The W D tractor is of the caterpillar type ; its engine develops 20 HP.

G. B.

- 475 - **Method of Fixing Mould Boards on Ploughs, Deutsche Last-Automobilfabric System.** — *Deutsche Landw Presse*, No 43, p 327 Berlin, June 1, 1921

The frame bearing the mould-board is fixed on the chassis in such a way as to be able to rise vertically, and slope backwards when the plough meets with any obstacle ; two compensating springs control the displacement and bring back the frame into its normal position.

G B.

- 476 - **Richter Hoe for Potato Ridging.** — *Deutsche Landw Presse*, No 35, pp 268-259. Berlin, May 4, 1921

In the present type of machine, the blades are adjusted to the slope of the sides of the ridges, by turning on a pivot inclined in the direction in which the machine is travelling. The new machine provides for a second movement, round a vertical axis. By this means, the blade is able to adapt itself both to the slope and to the height of the ridge, so that the edge is prevented from coming into contact with the plants.

G. B.

- 477 - **Working the Soil with a Disk Harrow.** — BIPPART, in *Deutsche Landw Presse*, No 53, p 400 Berlin, July 6, 1921

The author examines the different kinds of work executed with a disk-harrow, or pulveriser. It is a mistake to use this implement in

the spring for working the soil to a depth of 15 cm. The mass of soil is too much disturbed and as a result of the contact of the earth with the air, the water evaporation is intensified which is very injurious, especially as the spring is generally followed by a period of drought.

When it is necessary to make a layer of granular soil on the surface of the ground, such as is obtained with a rotary plough, the disk-harrow brings about this result with the expenditure of less energy than any other implement. The author mentions other cases in which it can be employed: fallow land that has been ploughed in the autumn should be disk-harrowed in spring to decrease evaporation and hasten the germination of weed-seeds. The disk-harrow is well adapted for the destruction of weeds and also for breaking up stubble after cereal crops have been carried.

G B

478 - **Renniger's Apparatus for Cleaning Seeds.** *Deutsche Landw. Presse* No 33, p. 255. Berlin, April 27 1921.

This apparatus is especially adapted for cleaning seeds such as those of the poppy, clover, etc. It consists mainly of a series of sieves of which the action is completed by rubbing plates.

G B

479 - **Breite Potato Sorter.** — *Deutsche Landw. Presse*, No 9, p. 222. Berlin, April 13 1921.

The rotating type of potato-sorter requires a very long cylinder for satisfactory working. In order to diminish the length of the apparatus and make it easy to carry when sorting is done in the field, and also easier to store, the drum is so constructed as to be capable of extension while folding together bellow-wise.

G B

480 - **Carlson Straw Press combined with Thresher.** — *Deutsche Landw. Presse* No 21, p. 163. Berlin, March 16 1921.

The press is placed at right angles with the thresher and its hopper receives the straw from the shakers. Thus the axle of the guiding pulley is perpendicular to the driving shaft of the press. The gearing apparatus is patented; it consists of a frame that can be applied either to the right or the left side of the press. The pulleys altering the direction of the belt can be regulated both for height and direction.

G B

481 - **Automatic Distributor of Oats for Horses, Mische System.** *Deutsche Landw. Presse* No 45, p. 313. Berlin, June 5 1921.

This apparatus includes a regulator, a braked motor and the oat distributor. It works without springs, the oats falling into a vertical hopper into which they are poured by a horizontal transporting canvass set in motion by the mechanism.

G B

482 - **Double Stroke Wind Engine.** — *CONTI M. Lezioni de la Facultad de Agronomía y Veterinaria*, Vol. III Part 3, pp. 294-306, figs. 5. Buenos Aires, December 1921.

An improved type of ordinary wind-engine invented by Félix ROJÁN and tested with complete success at the "Instituto experimental de Mecánica agrícola" of the Agricultural and Veterinary Faculty of Buenos Ay-

No 482, Fig 1

*Diagram of the Construction of a  
Double Stroke Wind Engine*

*G* = discharge pipe

res under the direction of the author. The improvement consists in the use of a double balance to control the working of 2 concentric piston-rods thus providing for a cylinder with double piston and hence with an up and down stroke, the one rod rising as the other falls. The weights of the rod and of the tube which acts as an external rod are equal and balance one another, thus obviating the difficulties caused in ordinary wind en-

No. 482, Fig. 2. — Mechanism of Double Stroke Wind Engine.

SECCION = Vertical section

FRENTE = Front view of mechanism.

A, cast-iron socket of armature. -- B, axle of wheel and pinions. — C counter axle of reducing cog-wheels. — D, insertion of external pinions which unite in axle F and communicate at F the motion of the rod V. — G insertion of the double central axle communicating the movement to the other tubular rod V<sub>1</sub> by means of the oscillating arm H. The guiding-rods M and N, control the oscillating arms in order to obtain a perfectly vertical and centric movement of the rods; the dotted lines show the radius of action of each oscillating arm when in motion.

gines by the weight of the single rod. The water thus raised flows without interruption and given equal wind velocity, is about twice as much as that obtained with an ordinary single stroke wind engine.

The armature of the machine is placed as usual on the top of the tower, in order to impart the rotatory movement of the sails (see fig. 1, p. 572); the wheel, helm, and the regulator, or automatic device for stop-

ping the engine are of the ordinary type. The axle of the wheel (see fig. 2, p. 573), rests on 2 supports and carries 2 pinions geared with the two cog-wheels that reduce and transmit the movement. The simultaneous and inverse movement of the 2 concentric axles is obtained by 2 rods meeting at an angle of  $180^\circ$ . The external rods work on 2 arms at the end of the axle of the cog-wheels and the central rod is attached to an eccentric axle connecting the 2 cog-wheels; the 2 rods have the same stroke, but in opposite directions.

F. D.

483 - **A Chest of the Funke Type, to be used in Testing Milk.** — WEISDEMANN, in *Deutsche Landw. Presse*, No. 33, p. 355, Berlin, April 27, 1921.

The author gives a description of a case containing all the apparatus necessary, including the separator, for making a rapid test of milk. The case measures  $54 \times 54 \times 36$  cm. and weighs 40 kg. The author has found this device very practical in use.

G. B.

484 - **A Mercury Vapour Current Transformer for use in the country.** — SIMON E., in *Deutsche Landw. Presse*, No. 17, p. 123, Berlin, March 2, 1921.

This apparatus transforms an alternating current into a continuous current. It is especially useful for owners of a continuous current electric plant who have the opportunity of connection with a central station having an alternating current. With the help of this apparatus, there is no necessity for change in the original installation. The author mentions several ways in which this current redresser can be used, and describes the cases where it can be employed with advantage.

G. B.

## RURAL ECONOMICS

485 - **Farm Organisation in Bohemia.** - BRDLÍK (Director of the Institute of Agricultural Accountancy), in *Bulletin du Ministère de l'Agriculture de la République Tchécoslovaque*, Year II, No. 4, pp. 25-27. Prague, Oct. 1 1921.

The Prague Board of Agriculture ("Conseil d'agriculture de Prague") in 1912 founded an Institute of Agricultural Accountancy whose duty it was to control, by means of accountancy, the farms with which it was associated. The farmer correspondents of the Institute supply their weekly reports on income and expenditure, fodder rations for the different domestic animals, and work done in the fields and on the farms. With these data as a basis, the Institute draws up the annual balance-sheet of the farm, which shows how it has been managed during the period. Since its foundation, i. e. in the course of 9 years, the Institute has compiled valuable information regarding the organisation of farms, details of income and expenditure of the landowners, etc.

The trend of farm organisation among the different types of farmers is shown in Table I, which gives the percentages of the various crops cultivated for each type and size of farm:

The figures in Table I do not allow a judgment as to the influence of the size of farms on the percentage of the various crops grown. Those of Table II are more interesting.

TABLE I. — *Percentages of the various crops cultivated.*

	Size of farms			
	2-5 ha	5-20 ha	20-100 ha	100 ha
	%	%	%	%
<i>Arable land:</i>				
1) In the beet growing district . . . . .	91	89	90	93
2) " " cereal . . . . .	85	81	80	80
3) " " potato . . . . .	79	79	80	84
4) " " forage . . . . .	61	77	71	77
<i>Garden:</i>				
1) Do. . . . .	5.4	2.1	3.5	2.3
2) Do. . . . .	4	1.9	1.7	1.1
3) Do. . . . .	2.4	2	1.3	1
4) Do. . . . .	1.9	0.9	0.6	0.3
<i>Meadow:</i>				
1) Do. . . . .	3	8	5	3
2) Do. . . . .	9	16	17	13
3) Do. . . . .	17	16	16	13
4) Do. . . . .	35	17	22	19
<i>Pasture:</i>				
1) Do. . . . .	0.3	0.7	0.8	2.2
2) Do. . . . .	1.7	1.6	1	5.9
3) Do. . . . .	1.7	2.8	2.3	1.7
4) Do. . . . .	2.1	5.9	6.5	4

The area sown with cereals, especially rye and oats, decreases with the increase of the root-growing areas (especially those of the sugar-beet).

TABLE II. — *Percentages of the various crops cultivated.*

Crops cultivated	Size of farms			
	2-5 ha	5-20 ha	20-100 ha	100 ha
	%	%	%	%
Cereals and pulse. . . . .	64	65	59	57
Root crops. . . . .	17	15	20	23
Kitchen-garden crops. . . . .	1	1	1.4	1.4
Forage crops. . . . .	18	19	20	19
	100	100	100	100

The part of the sugar-beet growing area which is under intensive cultivation increases surprisingly in comparison with the part under potatoes. In this district, potatoes form 50 % of the root crop in the group of farms of 2-5 ha, 36 % in those of 5-20 ha, 15 % in those of 20 to 100 ha, and 9 % in those of over 100 ha. In large holdings, the area of

TABLE III. — *Percentages of cereals and roots taken separately.*

Cereals	2-5 ha	5-20 ha	20-100 ha	100 ha.
	%	%	%	%
Wheat. . . . .	14	18	20	27
Rye. . . . .	41	35	31	23
Barley. . . . .	14	16	22	28
Oats and pulse. . . . .	31	31	27	22
	100	100	100	100

Root crops	2-5 ha	5-20 ha	20-100 ha	100 ha
	%	%	%	%
Potatoes. . . . .	74	66	44	40
Sugar beet. . . . .	20	22	48	60
Mongels and legumes. . . . .	6	12	8	—
	100	100	100	100

sugar-beet is about double that in smaller estates; the large holdings also produce the largest quantities of cereals (wheat and barley) for the market as shown in Table IV.

It will be seen that the largest farms grow smaller quantities of cereals and larger forage crops.

TABLE IV. — *Production of cereals and pulse.*

	2-5 ha	5-20 ha	20-100 ha	100 ha
	%	%	%	%
Wheat . . . . .	26	26	32	42
Rye . . . . .	35	29	21	13
Barley . . . . .	22	27	35	38
Oats and pulse . . . . .	17	18	12	7
	100	100	100	100

TABLE V. — *Subdivision of crops  
in the district of intensive cultivation of cereals.*

	2-5 ha	5-20 ha	20-100 ha	100 ha
	%	%	%	%
Cereals and pulse . . . . .	68	70	66	65
Root crops. . . . .	15	13	14	12
Kitchen-garden crops. . . . .	0.8	0.1	1.1	0.9
Forage crops . . . . .	16	17	19	22
	100	100	100	100

In the 3rd district, where potatoes are chiefly grown, with the increasing size of farms, the area under cereals decreases and that under forage crops increases; in the large holdings the area under root crops also increases.

TABLE VI. — *Subdivision of crops cultivated in the district where the potato crop is predominant.*

	2-5 ha	5-20 ha	20-100 ha	100 ha.
	%	%	%	%
Cereals and pulse . . . . .	65	62	59	57
Root crops . . . . .	16	16	16	20
Kitchen-garden crops . . . . .	0.9	0.5	1.7	0.8
Forage crops . . . . .	18	21	23	22
	100	100	100	100

The characteristics of the 4th district, where forage crops are chiefly grown, are shown in Table VII:

TABLE VII. — *Subdivision of crops cultivated in the district where forage crops predominate.*

	2-5 ha	5-20 ha	20-100 ha	100 ha.
	%	%	%	%
Cereals and pulse . . . . .	57	67	71	69
Root crops . . . . .	11	12	8	6
Kitchen-garden crops . . . . .	5.6	1.3	0.8	0
Forage crops . . . . .	26	20	20	25
	100	100	100	100

It will be seen therefore that on the largest estates the area under cereals increases considerably, while that under root crops and legumes decreases.

The author has also studied the influence of the size of farms on the number of draught and other animals. By estimating the work of oxen and cows on the same scale as the work of horses, using the coefficient 2 horses = 3 oxen = 5 cows, the data set out in Table VIII are obtained.

It will be seen that the need of draught-animals decreases with the increased size of farms and that large holdings make a greater profit from the work of draught-animals than small. Draught animals reduce the stores of forage which could be utilised in dairy-farming, meat production, etc., by other kinds of cattle.

Hence the table shows that the number of cattle decreases with the increased area of farms, and that this is especially the case with milch-cows and young cattle; the medium-sized farms are engaged chiefly in the rearing of young cattle.

TABLE VIII. — *Number of draught animals used on 100 ha of arable land.*

	Farms of 2 to 5 ha		Farms of 5 to 20 ha		Farms of 20 to 100 ha		Farms of more than 100 ha	
	Number of head	Work reduced to horse power	Number of head	Work reduced to horse power	Number of head	Work reduced to horse power	Number of head	Work reduced to horse power
Horses . .	2	2	9.4	9.4	9.8	9.8	4	4
Oxen . . .	4.2	2.8	8	5.3	8.8	5.8	12.6	8.4
Cows . . .	60	24	13.6	5.4	—	—	—	—
Total . .	—	28.8	—	20.1	—	15.6	—	12.4

TABLE IX. — *Live weight in kilograms of horned cattle not utilisable for work. Average per hectare of arable land.*

	2-5 ha	5-20 ha	20-100 ha	1000 ha
	kg.	kg.	kg.	kg.
1st district . . . . .	449	304	225	123
2nd district . . . . .	458	294	209	153
3rd district . . . . .	402	264	217	183
4th district . . . . .	572	272	236	153
Average . . . . .	446	285	218	145

TABLE X. — *Live weight in kilograms of cattle per hectare of arable land.*

	2-5 ha	5-20 ha	20-100 ha	100 ha
	kg.	kg.	kg.	kg.
Young cattle . . . . .	109	88	67	32
Fat cattle. . . . .	—	—	24	40
Cows . . . . .	287	164	109	67
Total . . . . .	396	252	200	139

TABLE XI. — *Live weight in kilograms of swine per hectare of arable land.*

	2-5 ha	5-20 ha	20-100 ha	100 ha
	kg.	kg.	kg.	kg.
1st district . . . . .	52	30	8	0.4
2nd district . . . . .	41	27	12	2.4
3rd district . . . . .	25	20	15	3
4th district . . . . .	14	13	17	4
Average . . . . .	37	24	12	1.8

Thus the larger the farm, the smaller the number of swine.

As for sheep and goats, it has been proved that sheep have a relative importance on medium-sized farms only and that goats are not found on large holdings.

TABLE XII. — *Live weight in kilograms of sheep and goats per hectare of arable land.*

	2-5 ha	5-20 ha	20-100 ha	100 ha
	kg.	kg.	kg.	kg.
Sheep . . . . .	—	1.1	3.3	2.9
Goats . . . . .	2.7	1.1	0.1	—

Poultry also decrease with increased area of farms as is seen in Table XIII.

TABLE XIII. — *Live weight in kilograms of poultry per hectare of arable land.*

	2-5 ha	5-20 ha	20-100 ha	100 ha
	kg.	kg.	kg.	kg.
Fowls. . . . .	5.6	3.5	1.8	0.2
Other kinds. . . . .	4.1	3	1.3	0.1
Total . . . . .	9.7	6.5	3.1	0.3

It is certain that these proportions between the different classes of domestic animals have an influence on the utilisation of fertilisers and forage, and consequently on vegetable and animal production.

I. — A study of the factors involved in the cost of producing milk for direct consumption in the small towns of the counties of Guilford and Forsyth. This study has been undertaken by the experimental agricultural station of North Carolina, in collaboration with the Dairy Division of the United States Department of Agriculture. The enquiry was begun in August, 1915, and lasted 2 years. During the first year, 13 farms were visited monthly, and in the second, 14; the annual production and the factors involved in the cost of production from 557 cows were registered during this period. The average production per cow was 2223 kg. of milk for the 1st year and 2233 kg. for the 2nd. The cost of forage and pasture was 54.8 % of the total cost of the milk production; wages amounted to 28.6 % and sundry expenses (including litter) to 16.6 %. The total cost of production does not include the farmer's remuneration; and this applies also to the 4 following items

In winter, 50.3 %, and in summer, 46.7 %, of the labour employed on the farm was devoted to milk production; the rest was employed in the refrigerating, bottling and transport of the milk to the consumer. About 18 % of the work was done by women and children, both in winter and in summer.

II. — The Agricultural Extension Service of the Purdue University, in collaboration with the Dairy Division, ascertained the cost of producing milk intended for the Chicago market, for a period of 2 years, beginning the 15th August, 1915, in the county of Porter (Indiana)

In 1915-1916 this Service registered the yield of 334 cows belonging to 16 herds; the average yield was 3119 kg. per head per year. The following year the yield of 404 cows from 21 herds was registered; the result being an average of 3169 kg. of milk per head, per year. The average percentage of fatty matter was 3.7. About the same proportion of cows were not in milk (12-13 %) both in summer and in winter. Births were almost equally distributed over the summer and winter seasons, being 87 per year per 100 cows.

(1) These works form part of a series of studies, all on the same plan for typical districts of several of the States of North America. The most important results of the first 4 were taken from another source and summarised in *R* July 1921, No 759, the article analysed contains other interesting data, which are completed by those of the above-mentioned summary — See also *R* Jan 1920, No 115 (*Fd*)

In the annual average the total cost of milk production was distributed as follows: forage 49.4 %; pasture 8.2 %; labour 19.5 %; sundry expenses 21.6 %; depreciation of cows 1.3 %. The calves were credited with 6.8 % of the total cost of the milk production as increased by the depreciation of the cows, and manure with 15.5 %. In winter, 80 % of the labour was employed in milk-production, and in summer, 75.5 %; the rest was used in handling and transport. Women and children performed 15 % of the total labour in winter and more than 19 % in summer.

III. — A study of the cost of milk production and the factors involved in the county of Skagit, about 70 miles north of Seattle (Washington State).

In the 1st year, the enquiry began in August, 1917, and covered 17 herds. In the 2nd year, it began in January 1919, and covered 18 herds. Each herd contained an average of 31.3 cows in 1917-1918 and 28.6 cows in 1919. In the general average for the 2 years, there was a yield of 3598 kg. of milk, with 3.66 % of fatty matter, per head per year. The majority of the cows were of the Holstein breed. Almost all the milk was sold to the condensing establishments, to which it was transported in motor lorries.

In winter, 115 kg. of manure per 100 kg. of milk produced were taken up in the stable; during the summer, when the cows were pastured during the day 13 kg. only per 100 kg. of milk were obtained; 3 % of the cows did not calve during the year, 55 % calved during the winter season and 42 % during the summer. The total expenditure (including depreciation of the cows) was distributed as follows: forage and litter 43.9 %; pasture 12.5 %; labour 23.5 %; sundry expenses 17.6 %. The depreciation of the herd was estimated at 2.5 % of the total expenses, and 4.4 % of the total value of the head of cattle.

Paid labour (chiefly that of professional milkers) was employed for 64.2 % of the work in winter and 59.2 % in summer. Women and children performed 10.2 % of the winter work and 13.8 % of the summer work.

For the keep of a bull for 1 year, 286 kg. of concentrated food; 2707 kg. of dry forage; 1392 kg. of fresh forage; 20 kg. of litter; 40.4 hours of labour, plus pasture and sundry items (buildings, implements, taxes, interest on capital invested in stock, veterinary expenses, drugs, disinfectants, etc.), were required.

IV. — A study on the cost of milk production in the county of Addison (Vermont) made in 1917-1918. The data were taken for the 1st year from 17 herds, containing on an average 26.1 cows, and for the 2nd year from 18 herds, containing an average of 22.4 cows. The cows were chiefly of the Holstein breed; the average annual yield of milk was 2382 kg. per head. The milk was conveyed to the central collecting stations, whence it was sent to New York for direct consumption. 41 quintals of manure per cow were taken up from the stable in winter, and 7 in summer; 15 % of the cows did not calve during the year; 27 % calved

during the period from 1st May to 31st October and 58 % during the rest of the year; the majority calved in the spring.

Forage and litter accounted for 49.4 % of the total cost of production (including the depreciation of the cows); pasture 5.5 %; labour 21 %; and other expenses 20.7 %. The depreciation of the herd was 3.4 % of the total cost. Manure was set off against 17.7 % of the total expenses, and calves against 5.5 %.

During the winter, 41.7 % of the work was carried out by the owners; 47 % was paid labour; and 11.3 % was done by women and children. In summer the corresponding percentages were 39.1; 42.4; 18.5. In winter, 79.9 % of the work consisted in production, properly so called, as distinct from handling and transport; in summer, 77.6 %.

For the annual maintenance of a bull, 152 kg. of concentrated food; 3044 kg. of dry forage; 1087 kg. of fresh forage; 122 kg. of litter and 37.7 hours of human labour plus the cost of pasture and sundry items, were required.

V. — A study of the factors involved in the cost of milk production in the parish of Tangipahoa (Louisiana) during the 2 years beginning with March, 1918. The data were taken from 14 farms during the whole period of 2 years, and from 8 others for 1 year; they amounted to 892.6 years of production or lactation, yielding, on general average, 1409 kg. of milk, which is sent to New Orleans for direct consumption. The Table given below shows the averages for the 2 years under consideration.

*Sundry expenses and quantities of food and work required for milk-production in the parish of Tangipahoa, Louisiana.*

	Concentrated food purchased	Grain produced on the farm	Leguminous hay	Other hay	Straw and stalks	Pressed green and other fodders	Manual labour	Horse labour	Litter	Pasture	Sundry expenses (1)
	kg.	kg.	kg.	kg.	kg.	kg.	hours	hours	kg.	dollars	dollars
<i>Per cow:</i>											
From Oct. to March	420	10	35	91	84	465	75.3	11.6	1.8	2.03	13.05
From April to Sept.	426	2	4	4	8	66	82.2	12.1	—	3.55	11.74
For the whole year	846	12	39	95	92	531	164.5	23.7	1.8	5.58	24.79
<i>Per 100 kg. of milk:</i>											
From Oct. to March	70.8	1.6	9.0	15.2	14.1	78.4	11.0	2.0	0.3	0.344	2.20
From April to Sept.	50.2	0.3	0.5	0.5	0.9	8.1	11.0	1.5	—	0.453	1.44

(1) Variations in the inventory value not included.

7820 kg. of manure per cow were taken up in winter and 626 kg. in summer. About 43 % of the cows calved in winter and 42 % in summer.

The forage and litter represented altogether 49.3 % of the total cost of production (including the depreciation of the cows); pasture represent-

ed 4.1 %; labour 24.2 %; other expenses 4.2 %. Manure was set off against 5.5 % of the total cost of production, and calves against 1.7 % (there having been little demand for calves on the market, this credit is rather high).

During the winter, 33.1 % of the work was done by the owners; 41.9 % was paid labour; 25 % was carried out by women and children. During the summer the corresponding percentages were: 28.2; 42.7; 29.1.

For the annual maintenance of a bull, 544 kg. of concentrated food; 353 kg. of dry forage; 511 kg. of fresh forage; 0.9 kg. of litter; 33.6 hours of manual labour, besides pasture and sundry items, were required.

## AGRICULTURAL INDUSTRIES

491 - **Modern Processes of Wine Making Technique.** — SANNINO T. A., in *Rivista di Ampelografia*, year II, No. 10, pp. 141-152 Leghorn, October 1, 1921.

INDUSTRIES  
DEPENDENT  
UPON  
VEGETABLE  
PRODUCTS

The report made to the Brescia National Congress of Wine-Growing (Italy), September 5-6-7, 1921.

WINE-MAKING WITH SULPHUR DIOXIDE (1). — Until quite recently, sulphur dioxide was used only in cellars for the preservation of wine that had already been made, except in the case of sweet wines. It is now, however, employed in wine-making, 10-20 gm. of potassium bisulphite being added per quintal of grapes in temperate climates at the moment of pressing, and as much as 30 gm. in hot climates when the alcoholic fermentation has reached its maximum.

This insures the action of good quality alcoholic ferments and the scent and flavour of the wine is improved; it is more highly coloured, if red grapes are used, and of a finer straw-colour if white ones are employed; in both cases the wine is clearer and keeps better. A great part of the sulphur-dioxide introduced is eliminated during the violent fermentation and hence no bad effects are produced.

The introduction of sulphur dioxide is specially advantageous when the grapes are of poor quality; it should not be used for good grapes grown on the slopes, especially if the wine is to be matured as maturation is hindered by its presence.

In hot climates the addition of sulphur dioxide induces complete fermentation, and replaces plastering, as practised in Sicily, and correction with tartaric acid as is customary in Apulia.

The author gives an account of research in the use of sulphur dioxide in wine-making, and refers to the works of P. CZEPPÉL (1888). Head of the Wine Vaults of the "R. Scuola Enologica di Catania", of Prof. U. RICCIARDELLI (of the "R. Cantina sperimentale di Riposto"), of MENSIO and PARIS in Italy, and of MARTINAND, ROOS, SEMICHON, ASTRUC, and VENTRE, in France.

(1) See *R. Nov.* 1917, No. 1061. (Ed.)

The introduction of sulphur dioxide facilitates the use of selected ferments.

Certain "associated" products are found on the market, such as JACQUEMIN bisulphite, and HUBERT sulphophosphate; these are mixtures of two substances, one of which liberates sulphur dioxide, while the other provides food-material, such as ammonium phosphate, for the alcoholic ferments.

The addition of sulphur dioxide at the time of manufacture increases the keeping capacity of the wines but does not protect them against "la fleur", or prevent their turning acid in the barrel when sold retail; the only remedy in both these cases is the introduction of carbon dioxide.

UNFERMENTED GRAPE PRODUCTS. — Fermentation is entirely prevented by adding to unfermented must 70 gm. of sulphur dioxide per hectolitre. If such must is poured into a concentrating apparatus, and distilled in a vacuum, the sulphur dioxide is first removed, and then the water, the resulting product being a concentrated must that can be used for many purposes.

The author mentions the BARBET apparatus which obviates the need of large plants, and the FUDO MONTI apparatus (1) in which concentration is obtained by lowering the temperature.

THE RAPID PRODUCTION OF SPARKLING AND THE QUICK MATURATION OF OTHER WINES (2), — The wine is pasteurised if necessary, or else heated to the best temperature for insuring rapid fermentation. The required amount of sugar and of selected ferments are added, and the wine is allowed to flow into large, closed vessels of enamelled iron. After ten days, the pressure of 6 atmospheres is reached, and then the wine passes automatically, and without any loss of carbon dioxide, into other enamelled or silver-plated receptacles. By means of the refrigerator it is cooled down to some degrees below zero to keep it as clear as possible. Sparkling wine is filtered without loss of gas, and when quite clear, passes into another vessel and thence into bottles, still retaining its gas. In Italy there are some CHARMAT plants already at work. This method can also be used in the preparation of sparkling Muscat which is more difficult to make than champagne.

The CHARMAT process for maturing wines is based on the use of high and low temperatures. The wine is pasteurised in an œnotherm, under pressure and in the presence of air, in order to allow the bouquet to develop; it is then cooled for a time at some degrees below zero and finally filtered and bottled.

MONTI devised a rapid maturing process which consists in passing a current of air through wine cooled at 2-4 degrees below zero, but this method does not suit all kinds and cannot for instance be employed in the case of Marsala, as it destroys the characteristic bouquet.

(1) See R. 1914, No. 946; R. 1917, No. 857; R. 1920, Nos. 249 and 909. (Ed.)

(2) See R. Oct., 1921, No. 1042; R. July 1921, No. 756. (Ed.)

The author is of opinion, that the adoption of the CHARMAT and MONTE processes will greatly stimulated the progress of the already extensive Italian wine-industry.

492 - **Experiments in Fermenting Kaki Fruits.** — MANZONI I. (R. Scuola di Viticoltura ed Enologia, Conegliano), in *Le Stazioni sperimentali agrarie italiane*, Vol. LIV, Parts 7-10, pp. 284-288 Modena, 1921.

The kaki has the advantage of being very hardy; it is not an exacting plant and produces a heavy, regular crop. One hectare can bear 350 trees, each yielding 1 quintal of fruit. As the fruit can only be directly consumed to a limited extent, and when perfectly ripe is very rich in sugar, the author tried to find out whether it could be made useful by fermentation.

Kaki fruits gave on analysis 16 % of reducing sugar but only 0.4 per 1000 total acidity, hence the author in order to obtain satisfactory fermentation made the following additions:

1) bi-tartrate of potassium 5.5 per 1000 + tartaric acid 1 per 1000 + citric acid 1 per 1000. In this manner, a total acidity of 4.4 per 1000 was obtained expressed as tartaric acid.

2) one quart of sterilised white grape must (with 22 % of sugar and 12 per 1000 acidity) + bi-tartrate of potassium 5 per 1000 + tartaric acid 1 per 1000 thus making a total acidity of 3 per 1000 expressed as tartaric acid. In both cases, the selected wine-making ferments were added and fermentation took place at 22° C.

The process began with a clearly marked separation of the liquid part and the spongy layer above it. On the fourth day, while fermentation was still active, the mixture was passed through a cloth, 74 % of liquid being thus obtained; a yield of 80 % of must could therefore be expected if industrial presses were employed. The must was then allowed to ferment slowly and was cleared with tannin and gelatine.

The results of the analyses made when fermentation was complete were as follows:

1) Wine from kaki fruits alone: alcohol 8.9 %; dry extract 22.42 per 1000; acidity 4.7 per 1000; ash 2.64 per 1000.

2) Kaki wine with  $\frac{1}{4}$  grape must: alcohol 9.5 %; acidity 4.12 per 1000; slightly sweet.

The wine remained sound and clear. When tasted, the first was clear and of a pale straw colour tending to greenish. It had an alcoholic scent mixed with an almost aromatic fruit bouquet, a slightly acid, dry, rather bitter taste which was flat and not vinous. The second, made with the addition of grape must was very clear, of a light golden-yellow colour, and with peculiar scent of flowers. It had a pleasant sweetish, slightly acid flavour which was stronger and cleaner than that of the wine made from kaki fruit alone. It had in fact the taste of a good cider without any of its disagreeable qualities.

"Wine" made from kaki fruit without any admixture of grape must yielded a good vinegar with 4.89 % total acidity. A 45° brandy was

obtained from the "wine" by distillation with a scent resembling that of an ordinary pomace brandy and tasting like cider brandy.

These results show that it is technically possible to make good cider by the addition of grapes or other fruits to kakis, or to obtain a satisfactory product by the distillation of "wine" made from kaki fruits alone. It is an interesting fact that the kaki tree is much less difficult to grow than the cider apple-tree and yields a larger crop per acre. F. D.

493 - **The Raw Materials used in the Italian Alcohol Industry.** — Sessa L., in *Giornale di chimica industriale ed applicata*, Year III, No. 12, pp. 563-564. Milan, December 1921.

The following Table gives the number of *hectanhydres* of the various kinds of alcohol made in Italy from 1906-1907 to 1919-20 from different raw materials. The figures refer in each case to the fiscal year dating from July 1 to June 30, and have been taken from the statistics of the taxes on alcohol manufacture published by the Italian Ministry of Finance.

An examination of this Table brings out the dominant feature in the Italian alcohol industry, viz., the great variation from one year to another in the raw material used which admits of a very simple explanation. Alcohol can be manufactured from virous matter or from substances containing starch or sugar; there is thus a wide field of selection, and cereals, beets or wine are employed according to the condition of the markets. The raw materials for the manufacture of alcohol may be divided into 2 categories.

*Essential materials*, viz., those that can be used for no other purpose such as spoilt cereals, pomace of various kinds, wines that have gone sour, surplus wine in years of over production, molasses etc.

*Optional materials* viz. those only occasionally used for making alcohol when the conditions of the market permit, such as sound cereals, beets, fruits etc.

Naturally it is the former class that first supply the alcohol market and sometimes even over-stock it. The production of molasses alcohol keeps pace with the development of the sugar industry; immense quantities of wine alcohol are available in years of superfluous wine-production such as 1907-1908-1909 while the amount of pomace alcohol remains constant and is in correlation with the vintage season.

The consumption of alcohol in Italy during the pre-War years reached a maximum of 350 000 *hectanhydres*.

The optional materials are used to a limited extent only, according to cost, thus cereal and beetroot alcohols are employed alternatively to make up the annual deficit.

Under the head of various substances are included fruit in general (dried fig, dates, carobs etc.). They are not much used as a rule, but were sent to the distilleries in considerable quantities during the War and in the years immediately following, when the alcohol market underwent a serious crisis owing to the absolute dearth of raw materials and the abnormal stocks of these fruits in hand due to the prohibition of all export-

tation. Under ordinary circumstances fruit and carobs can be more advantageously used, and they are only sent to the distillery when the price of alcohol is very high *c. g.* 900 lire per *hectanhydre*, exclusive of tax.

With free competition, the price of alcohol is fixed by the cost of the best raw material available in unlimited quantities. To avoid over-production, the price of alcohol made from the first class of materials must be regulated by this price and always kept below it. Normally the price of alcohol depends upon the price of maize, which can be obtained in great quantities and is highly estimated throughout the world. Sometimes, however, the price is governed by the cost of beetroots, but to a less extent, the beet being a seasonal product.

495 - **Oil from the Pips of French Grapes.** — DE FAYARD, J., in *Revue de Viticulture* Year 28, Vol. V, No. 1635, pp. 480-487. Paris, December 29, 1921.

From the various analyses of grape pips made by the author at Charente, the following oil-content percentages were obtained: Folle Blanche 10 to 12.50 — Saint Émilion 9 to 11.3 — Colombard 10.5 to 12. The amount of oil present would seem to be correlated with the ripeness of the grapes.

The physical and chemical constants of the 2 samples of oil prepared by the author by extraction with carbon tetrachloride were as follows:

	I	II

496 - The Utilisation of the Residues of Oil Extraction from Olives (1). - DR MANJARRÉS, R., in *La Revista Vinícola y de Agricultura* N.º 4 pp. 31-40. Zaragoza February 16, 1922.

More than 2 years ago, the author in collaboration with Count DE CASA CHAVES, Director of the Regional Mineralogical Museum of Cordova, started research work upon the systematic utilisation of the residues from olive-oil factories. When it is realised that the oil industry in Spain produces an average of 200 000 tons of exhausted pomace and that owing to the scarcity of forests the products of wood distillation find a ready sale, it can readily be understood that the distillation of this residue may be very profitable.

Distillation can be carried out in closed vessels differing considerably from those usually employed, for the pomace can be closely piled so as to leave no space for the free escape of the volatile substances. According to the authors' experiments from one ton of pomace may be obtained 200 kg of charcoal in practically powder form and 160 cub. m. of complex and very combustible gases. The condensed liquids consist of acetic acid, alcohol and ammonia. The acetic acid is separated with milk of lime, as in the distillation of wood. For the separation of the alcohol from the ammonia, superphosphate of lime must be used, by this means a phospho-ammoniacal fertiliser is obtained and the alcohol is liberated.

One ton of pomace gives 40 kg acetic acid, 80 kg of tar and 17 litres of methyl alcohol. The charcoal and gases supply fuel for the distilling apparatus. In large factories briquettes can also be made of the tar and charcoal dust. The ashes form a fertiliser for the olive-trees.

The blackish, turbid liquid deposited at the bottom of the vessel under oil-presses is called *caux d'enfer*, and is of very variable composition according to the oil-factory. The amount produced in Andalusia may be estimated at 300 000 tons.

From one ton may be obtained 15 litres of rectified ethyl alcohol, 3 kg ammonium sulphate and a small variable quantity of an innocuous, red, colouring substance that can be used for the coloration of syrups, liqueurs etc. The *caux d'enfer* must be subjected at once to alcoholic

(1) See R. Dec. 1915 No. 125; April 1916 No. 115 (Id.)

fermentation ; from the distillation residue other substances can be obtained by the ordinary processes

On evaporation the resulting liquid, deposits potassic salts, and if the semi-fluid residue is subjected to distillation, charcoal and gases are obtained, but it should be noted, that during the process the residue increases in volume, and the vessels used must therefore be of a special shape

The process is remunerative provided that 1) large amounts of material are used, 2) the residues are utilised for fuel, 3) all the escaping heat is turned to account, 3) economical evaporators are employed

497 - **Economic Value of Sunflower Oil : Tests made in Great Britain.** - See No 431 of this Review

498 - **Variations in the Percentage of Fat in Successive Samples of Cows Milk** (1). - RAGSDALE A C, BRODY S and FERNER, C W in *Journal of Dairy Science*, Vol X, No 5 pp 448-450 Baltimore, September 1927

INDUSTRIES  
DEPENDENT  
UPON ANIMAL  
PRODUCTS

The fact that successive samples of milk drawn from a cow gradually increase in fat content, has long been known and was formerly explained by supposing that the fat being lighter rose to the top of the milk cistern and ducts

This gravity theory was however discarded as a result of the observations of HEDLICHAY, who found that the difference in the volume of the udder before and after the evacuation of milk is much below the volume of milk given by a cow during one milking, and consequently inferred that a large part of the milk is secreted during the process of milking. The authors describe their own experience which may contribute to an explanation of the phenomenon. The right front quarter of a Jersey cow producing about 20 pounds of milk per day was milked under the following conditions

*Amount of Fat in Successive Fractions of Milk*

Sample No	Cow			Cylinder	
	Upon coming into barn	After standing - hours	Standing - hours and manipulation	After standing 1 1/2 hours	After standing 3 hours
1	31 %	14 %	63 %	44 %	16 %
2	32	15	61	54	27
3	47	19	64	57	36
4	54	30	65	58	42
5	59	34	65	59	49
6	66	41	68	60	54
7	69	48	72	60	59
8	65	78	75	63	68
9	68	110 (about)	82	67	120

(1) See *R* June 1920, No 670 (1d)

1) immediately on coming into the barn from the pasture, 2) after standing quietly in the barn for two hours, 3) after standing in the barn for two hours followed by a thorough massaging and manipulation of the udder for a few minutes for the purpose of "mixing" the milk withur, if possible. The milk in each case was milked into a 100 cc cylinder and fat determined in each of the 100 cc fractions. For comparison determinations were made on the variations of fat in successive 100 cc of milk drawn from a 900 cc cylinder of the usual dimensions after standing respectively for 1 ½ and 3 hours. The results given in the Table show that, within given limits, the longer the cow stands quietly the greater the variation in the fat content of the successive fractions of the milk. The curves of variation in the cylinder and udder are strikingly similar.

**499 - Brown Glass Milk Bottles and their Use in preventing Milk from Acquiring abnormal Flavour and Odours due to the Action of Light.**

HAMMER B W  
and CORDES W A in *Advance Sheet of Research Bulletin of Iowa Agricultural College*  
summarised in *The Creamery and Milk Plant Monthly* Vol X No 6 pp 324  
Chicago, 1911

The authors have made a comparative study of the effect produced upon the colour, flavour and bacterial content of milk by placing it in white and in coloured bottles respectively. The results proved that sunlight produces abnormal flavours in milk and cream, whence the necessity of keeping bottles of milk, even in winter in a special covered chest or under a blanket.

Though brown milk bottles prevent these changes, their use cannot be advocated, because they make it difficult to see the sediment or the cream line, thus preventing whole milk being distinguished from milk that has been more or less skimmed. Milk kept in brown bottles has also a higher bacterial content than milk in ordinary bottles, which is in part due to the higher temperature of the brown bottles and also to the fact that light has a decided influence in keeping down the number of bacteria in white bottles. In fact if part of the same milking is exposed to sunlight in ordinary bottles and the rest kept in the dark in similar bottles, it will be found that the bacterial content is lower in the exposed milk, although the temperature is higher.

From the general results of their observations, the authors have drawn the following conclusions:

Sunlight has a pronounced influence on the flavour of milk and cream, with sufficient exposure a definite tallowy flavour was produced, and with less exposure a distinct sour flavour developed.

Sunlight is observed to produce an abnormal flavour, sometimes tallowy and sometimes otherwise, in other dairy products, such as ice cream, evaporated milk, skim milk and starters. When milk or cream has acquired a tallowy flavour from exposure to light, it is communicated to the butter which does not lose it by keeping.

When there was an increase in acidity in milk exposed in ordinary bottles and brown, the increase was generally greater in the brown bottles.

The colour of milk exposed to sunlight does not alter nearly as much in brown as in colourless bottles, in which the milk after a time shews a chalky dead-white appearance and produces butter of much lighter colour. Light has a greater influence on a milk low in fat content than on a milk with a high fat content.

Exposure to air had evidently some influence on the development of a tallow flavour.

The tallowy flavour in milk exposed to sunlight in white bottles apparently decreased somewhat as a result of storage at low temperature.

F. D.

**500 - Influence of Foreign Matter upon the Number of Bacteria in Milk.** — HARDING, H. A., PRUCHA, M. J., KOHMAN, F. F., WLETER, H. M., and CHAMBERS, W. H., in *Journal of Dairy Science*, Vol IV, No 5, pp 430-447 Baltimore, September 1921.

It used to be thought that the absence of foreign matter or dirt had a great influence upon the bacterial count of milk, but the results of recent research tend to show that the cleanliness of milk in this respect is of much less importance than has been supposed. The existing divergence of opinion however encouraged the authors to make an experimental study of the question at Urbana, the Illinois Agricultural Experiment Station.

The results of their investigations have shown that :

Practically all the dirt entering the milk at a farm is introduced during the operation of milking.

The use of a small-topped milk-pail materially reduces (from 20 to 40 %), the amount of impure matter that finds its way into the milk.

The weight of the impurities entering the milk during the milking process is surprisingly small. Even when the cows were extremely dirty and milked into an open-topped pail, the dirt in the unstrained milk amounted to only about 10 mgm. per quart. When the conditions were comparable to those of ordinary dairies and the small-topped pail was used, the dirt in the milk was less than 5 mgm. per quart.

The kinds of impurities which fall into the milk vary with the condition of the coat of the cow. With hand-milking the entrance of some hair and dandruff is practically unavoidable, though the amount may be reduced by regularly brushing the coat of the animal. If flank or udder is soiled with dried manure or other dirt, some may also find its way into the milk.

Thorough straining removes the hair, dandruff, and larger particles which form 75 to 90 % of the visible dirt. Undoubtedly some of the impurities go into solution in the milk, but the amount is so small that the authors did not succeed in measuring or detecting it.

The increase in the bacterial count due to the entrance of dirt into the milk varies widely with the nature of the dirt. Hair and dandruff from clean cows have much less effect than from dirty cows.

On extremely dirty cows there were 1500 million germs per gram of dirt. Under the worst conditions when the dirt in the milk amounted

to 10.8 mgm. per quart, the increase in the number of bacteria was about 17 000 per cubic centimetre. Under similar conditions, except that a small-topped pail was used, which reduced the dirt to 8.1 mgm. per quart, the bacterial count due to dirt fell to 13 000 per cubic centimetre.

The use in warm weather of clean utensils which have not been promptly and thoroughly dried results in the immediate increase of the germ count of the milk varying from 30 000 to 1 000 000 per cubic centimetre.

In summer milk drawn in the morning and delivered from the farm to the milk plant has an average bacterial count of at least 50 000 per cubic centimetre. After the first 6 to 10 hours, the growth of the microorganisms begins and their number may rapidly increase.

In view of these facts it is clear that the variations due to dirt which occur in the bacterial count, and may be as large as 17 000 per cubic centimetre, will be less important than other factors at any rate in summer.

When the time interval permits growth, it is impossible to judge, on a basis of bacterial count, the conditions of cleanliness in the production of a given sample of milk.

An examination of milk based on the germ count does not therefore protect the consumer. In order to prevent the sale of milk contaminated by impurities it is necessary to determine the impurities actually present by measuring the sediment formed, or by filtering the milk through cotton and weighing the filter before and after filtering and drying. By this method the data obtained are a little higher than they are in reality.

F. D.

501 - Type of Lactic Acid produced by Starters and by the Organisms isolated from them. — HAMMER, B. W., in *Advance Sheet of Research Bulletin 56, Iowa Agricultural Experimental Station and the Creamery and Milk Plant Monthly*, Vol. X, Part 8, p. 24 Chicago, 1921

Recent work has shown that starters are not pure cultures of *Streptococcus lacticus* as is commonly supposed. HAMMER and BAILEY showed that pure cultures of the *Streptococcus* do not produce a volatile acidity at all comparable with that obtained by a good starter and that starters generally contain an associated organism which when grown in combination with *S. lacticus*, yields a volatile acidity essentially the same as that produced by a satisfactory starter. STORCH found that organisms, which he calls  $\alpha$  bacteria, are present in starters and that these play a part in the production of a good cheese. BOCKHOUT and OTT DE VRIES reported the isolation from starters of organisms that in combination with lactic acid bacteria produce the characteristic aroma.

It can be proved that starters are not pure cultures of *S. lacticus*, by ascertaining the type of lactic acid found in a starter and comparing it with the type produced in milk by pure cultures of *S. lacticus*.

This method was adopted by the author, who also determined the type of lactic acid produced when the associated organisms are combined with *S. lacticus*.

It has been shown by the work of a number of investigators (HEINEMANN, SUZUKI, HASTINGS and HART, ORLA JENSEN), that *S. lacticus* only produces dextrogyric lactic acid, at least under the usual conditions of growth.

The author examined a number of starters that had been used in a creamery and found that they did not produce pure dextrogyric acid, but a mixture of active and inactive acids. Starters are thus not pure cultures of *S. lacticus*, and the associated organisms are undoubtedly important in producing a type of non-dextrogyric lactic acid. The results obtained suggest that the associated organisms are able to transform dextrogyric lactic acid into levogyric lactic acid. F. D.

502 - Connection between the Number of the Bacteria in the Milk and the Quality of the Cheese obtained. — HUCKER, G. J. in *New York Agricultural Experiment Station, Geneva, Bulletin No. 486*, 19 pp, 8 figs. Geneva, N. Y., 1923.

This paper is the first of a series of studies on the bacteriology and ripening of cheeses and the connection between this ripening and the bacterial flora of the milk. The data upon which this study is based were collected during the winter of 1920 in a cheese-factory near Philadelphia, where whole milk Cheddar cheeses of the "Young American" type were manufactured. The counts of the bacteria present in the milk were made on samples taken from the milk supplied by 25 members of the cheese factory and on samples taken from the cauldron; in some cases the number of bacteria was estimated from the acidity.

It was found that there is no connection between the bacterial content of the milk and number of marks accredited to ripe cheese, although milk with the maximum of microorganisms (12 to 14 million per cc.), tends to make better cheeses of a constant type, whereas milk with few bacteria produces cheeses of variable quality.

The number of bacteria present in the milk does not appear to have any effect upon the amount of cheese produced.

The character of the species of bacteria in the milk intended for cheese-making is of much greater importance than their number; hence milk intended for the cheese factory should not be judged from the bacteriological standpoint in the same manner as milk to be drunk in its natural condition. F. D.

503 - Chemico-Bacteriological Study of Different Qualities of Silaged Forages (1). — HUNTER, C. A. (Pennsylvania Agricultural Experiment Station), in *Journal of Agricultural Research*, Vol. XX, No. 7, pp 767-780, diagrams 6, bibliography of 20 works Washington, 1921.

The object of these researches was the study of the nature of the fermentations arising in a mixture of several silaged forages and thus to make

(1) For other studies on silaged forages see: R. Jan. 1916, No. 100; R. Feb. 1916, No. 232; R. Feb. 1918, No. 221; R. Jan. 1919, No. 105; R. Feb. 1919, 257; R. July-Sept. 1919, No. 1010; R. July-Aug. 1920, No. 802; R. May 1921, No. 471; R. Sept. 1921, No. 932. (Ed.)

a new contribution to the study of the still much discussed question of the agents which cause the transformations to which such forages are liable. It was originally believed that these changes were due to the enzymes present in the plants, later they were attributed to bacteria, but at the present time some investigators are inclined to think that enzyme and bacterial action both come into play, although they consider the former to be the more important agent. The hydrolysis of plant proteins, which during fermentation accompanies the increase in volatile and non-volatile acids and the formation of ammoniacal nitrogen, seems to be induced first by enzymes and afterwards by microorganisms.

The forage silaged consisted of: 1) vetch + oats; 2) maize; 3) maize + soya. The two latter were compared and the product was analysed from the bacteriological and chemical standpoints at different stages of ensilage.

These analyses showed very little difference in the fermentation processes in the silaged forage, whether vetch and oats, maize alone, or maize and soya. In the forage consisting of maize only, the bacteria of the *bulgaricus* group were more numerous than in the mixed forages.

The analyses also proved that micro-organisms are the chief fermentation agents in forages to be made into silage; enzymes however play a part in the hydrolysis of the proteins with the formation of aminic nitrogen. The production of acids is due to the micro-organisms, while in the formation of ammonia both enzymes and micro-organisms are equally active. Yeasts appear to have little effect on the fermentation of silaged forage, except during the first few days.

### GENERAL INFORMATION

504 - **Government Enactments in Formosa regulating the Importation and Exportation of Plants.** - INTERNATIONAL INSTITUTE OF AGRICULTURE *Textes législatifs de l'année 1921*, No. 30 (1).

LEGISLATION  
AND  
ADMINISTRA-  
TION FOR  
PLANT  
PROTECTION

1) Edict of April 15, 1921, No. 5 promulgating the law dealing with the importation and exportation of plants. - *Kwampô* (Official Journal), No. 2665. June 20, 1921.

2) Decree of September 10, 1921, No. 142, containing the text of the law controlling the importation and exportation of plants. - *Kwampô*, No. 2753. October 4, 1921.

In the second decree the plants and portions of plants intended both for importation and exportation for which inspection is required are specified. It contains the rules to be observed by any person intending to import or export such plants or portions of plants, as well as the powers conferred upon the officers of the Phytopathological Service; it establishes the conditions under which the importation of injurious diseases and insects etc., may be authorised. Ten forms are appended, *viz.*, request for the inspection of plants or portions of plants to be imported from abroad or from other parts of Japan; request for the inspection of plants or portions of plants to be exported abroad or to other parts of Japan; request for permission to import from abroad or from other parts of Japan, injurious diseases or insects; request for the inspection of injurious diseases or insects to be imported from abroad or from other parts of Japan; request for the inspection of plants or portions of plants imported from abroad (or from other parts of Japan), by means of the ordinary post; label certifying inspection; stamp certifying inspection; certificate of origin for inspection of nursery-garden products; certificate of origin

(1) The text of the decrees of the Formosa Government, and the texts of other enactments to which reference is made later in this article are to be found reproduced in their entirety in the collection of the *Textes législatifs* published in 1921 in separate volumes by the International Institute of Agriculture

The object of this collection is to make known immediately the most important legislative measures referring to agriculture that have been enacted in the different countries of the world. These measures, together with all those not contained in the *Textes législatifs*, will afterwards be included, as usual, in the *International Year Book of Agricultural Legislation*, also published by the International Institute of Agriculture. (Ed.)

for nursery-garden products packed with soil ; label certifying that inspection has been omitted , stamp certifying that inspection has been omitted.

3) Decree of September 10, 1921, No 144 fixing the fifteenth day of September 1921 as the date on which the law controlling the importation and exportation of plants comes into force — *Kwampô*, No 2753, October 4, 1921

4) Decree of September 10, 1921, No 158 defining the powers of the Plant Inspection Station of the General Government of Formosa — *Taiwan noji hô* (Agricultural Review of Formosa) No 179 October 1, 1921

On September 15, 1921 a Government Plant Inspection Station under the supervision of the Director General of Production was established in Formosa. This Station is charged with the inspection and control of the exportation and importation of plants as prescribed by the relevant regulations. It will also undertake studies and scientific research work on injurious diseases and insects. The Governor shall have the power to establish Sub-Stations in suitable places, and to endow them with certain of the powers of the Central Station.

5) Official Order of September 10, 1921, No 136 appointing the post-offices to carry out the provisions of Art 13 of the regulation relating to the control of the importation and exportation of plants — *Taiwan noji-hô*, No 179 October 1, 1921

The order prescribes that ' the post-offices appointed for this purpose shall — when they have received or accepted for dispatch postal packages containing goods subject to inspection in accordance with the provisions of the regulations governing the control of the importation or exportation of plants — notify the Station of Plant Inspection or one of its Sub-Stations. The inspection of the packages shall be carried out in the presence of the postal official '.

6) Official Order of September 10, 1921, No 137, fixing the amount to duty to be paid pursuant to Art 4 of the law dealing with the control of the importation and exportation of plants — *Taiwan noji hô*, No 179 October 1 1921

According to Art 4 a fixed fee shall be paid for the inspection of citrus fruits intended for export to Japan

7) Decree of September 10, 1921, No 143 fixing the places where the inspection prescribed by the law relating to the control of the importation and exportation of plants shall be carried out. — *Kwampô*, No 2753 October 4, 1921

The full text of the law of March 25, 1914, No 11, which deals with the control of the importation and exportation of plants is also added for purposes of reference

**505 - Decree of April 7, 1921, No. 148, Respecting the Control of *Chrysophlyctis endobiotica* in Czecho-Slovakia.** — *Sbírka zákonů a nařízení*, No 31, April 16, 1921 (Cfr. *Textes Législatifs*, etc., No 12)

The importation into the Czecho-Slovakian Republic of potatoes attacked or suspected of being attacked by "canker" (*Chrysophlyctis endobiotica*), as well as their transport through the country are prohibited. All potatoes imported into Czecho-Slovakia or to be conveyed through the country, are subjected as soon as they reach the frontier, to inspection by the special Phytopathological Commissions which have their Headquarters at specially appointed Experiment Stations. The Decree defines the duties of these Commissions of which the members are appointed by the Ministry of Agriculture.

All consignments of potatoes from abroad must be provided with a copy of the immunity certificate issued by a State Experiment Station, or by a Public Experiment Station of Phytopathology in the country of export.

Every potato grower or land owner is required to notify immediately any case or suspected case of "canker" to the recognised Communal Authority who will in turn at once forward the notification to the Experimental Station of the zone where the case or suspected case has occurred. The potato grower or land owner is further required to forward for gratuitous inspection, a sample of the potatoes to the recognised Experiment Station, in order that all necessary measures may be taken. Pending the conclusion of the examination and further instructions, the potatoes may not be removed.

Districts where the presence of "canker" has been reported or suspected, are declared to be "infected districts" and the potatoes growing therein may not for any reason be lifted except by direct order of the Ministry of Agriculture.

Potatoes infected or under suspicion of infection by "canker" cannot be used for "seed."

The Ministry of Agriculture may proceed after indemnifying the owner, to the confiscation of the diseased potatoes and may prohibit until further notice the raising of potatoes on infected land or land on which infection is strongly suspected, and in this case, compensation may be granted. Should the grower or holder of the potatoes have omitted to declare the presence of "canker", he is not entitled to any indemnity or compensation.

The Experiment Stations that are the Headquarters of the Phytopathological Commissions are responsible for carrying out the measures for controlling the disease.

**506 - Decree of October 25, 1921, Respecting Insectivorous Birds and Bird-Catching, in Belgium.** — *Monsieur belge*, No 315, November 11, 1921 (Cfr. *Textes législatifs*, etc., No. 23)

A list of the insectivorous birds that may not, at any season of the year be caught, killed or destroyed, exposed for sale sold, or bought in Belgium, or conveyed through Belgium to other countries

[503-506]

The decree contains the regulations governing bird-shooting, bird-catching, the use of and trade in various birds not included in the above category

G T

507 - **Law No. 20 of July 26, 1921, Relating to the Control of the Pink Boll Weevil and of the seed of the Cotton Plant' in Egypt.** - *Journal Officiel*, No 70, August 1, 1921 (Cfr *Lexles leiskutsi* etc, No, 9)

Every year after the harvest, and at latest previous to the dates that will be fixed annually for each district, or zone by the Ministry of Agriculture, the roots of the cotton plant, of "til" (*Hibiscus cannabinus*) and of "bamia" (*H. esculentus*), shall be removed from the ground or cut down below the level of the soil so that they are unable to send out fresh shoots. Within the same space of time all bolls containing seed found lying on the ground ought to be collected and destroyed.

The Ministry of Agriculture has also the power of ordering that all the capsules remaining on the cotton-plants and *Hibiscus* shall be gathered and at once destroyed, even before the dates that are to be fixed annually.

The cotton of each crop must be ginned before the 1st of May subsequent to the harvest.

All the seed of each crop immediately after ginning must be subjected to special disinfection in accordance with the regulations of the Ministry of Agriculture. Without the permission of the Ministry no cotton, cotton seed cotton waste residues etc with the exception of ginned cotton and such seed as has been thoroughly disinfected by the above-mentioned process, shall be removed from the premises where the ginning operations are carried out.

## DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

509 - **Sulphate of Iron and Perochloride of Iron in the Treatment of Chlorosis of the Vine (1).** - I RICHIELLI in *La Propa andu Agricola* Series II Year XIII No 15 pp 206-209 Bari 1921

In treating "chlorosis" of the vine with sulphate of iron it is necessary according to the author, to insure that this salt exerts a rather prolonged action on the root system of the host plant. For this reason instead of applying a solution of iron sulphate to the soil around the diseased vine, it is better to use it in the form of powder which should be well mixed with soil and spread round the vine-stock at a distance of 50-60 cm. The soil is then lightly watered for some days which causes the salt to dissolve gradually and provides the roots with a constant supply of

(1) See R March 1920 No 366 (Fd)

a weak solution, which will not become too concentrated. For this treatment 250 to 300 gm. of sulphate of iron are sufficient.

Better experimental results, as regards efficacy, rapidity and economy, were obtained by the author in the treatment of chlorosis with perchloride of iron than with sulphate of iron if very dilute solutions were employed.

The author advises that perchloride of iron be prepared and applied in the following manner.

A 2 % solution is made by adding 10 to 12 gm. of perchloride of iron to 5 or 6 litres of water. This mixture is poured into a circular trench dug round the vine-stock at a distance of from 50 to 60 cm., in order to get as near as possible to the roots and the trench is afterwards filled in with soil.

By the adoption of this method severely infected vines have been permanently cured, whereas others which were treated with sulphate of iron and appeared to have recovered became chlorotic again after some time had elapsed.

### DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

510 - Reduced Yield of chief Crops, due to Fungoid Diseases, Insects and Animal Pests, in the United States of America. — See No. 370, of this Review

GENERAL

511 - Insufficient Phosphatic Fertiliser a Factor favourable to the Development of Rice Diseases. — See No. 411 of this Review

512 - Varieties of Potatoes resistant to *Synchytrium Solani* in Great Britain (1). — CUTHBERTSON W., in *The Gardener's Chronicle*, Series 3, Vol. LXXI, No. 1836, p. 104. London, March 4, 1922.

RESISTANT  
PLANTS

During the summer of 1917 many potato fruits were gathered in some large fields in Scotland. In each case the fruits were taken from near the centre of extensive zones so that it was probable that the flowers had been self-fertilised and not contaminated by the pollen of other varieties.

The seeds were sown in the spring of the following year, and in October the tubers produced by each of the plants grown from these seeds were lifted.

In the spring of 1919, the six best tubers of each of the varieties used in the experiment were planted at Ormskir. At the harvest at the end of September, careful note was taken of the immunity of the tubers to *Synchytrium Solani*.

From the numerous data thus obtained attention is drawn to the varieties Priory Queen, Favourite and Admiral which all belong to the Abundance type noted for its marked resistance to the parasite.

- 516 - *Fusarium* sp. a Deuteromycete, the probable Cause of Disease of the Leguminosae, *Crotalaria juncea*, and *C. usaramoensis*, in Tonkin (1). — VINCENS F., in *Bulletin agricole de l'Institut scientifique de Saigon*, Year III, No. 12, pp. 381-384, Saigon, December 1921.

At the end of September 1921, the Phytopathological Laboratory of the Scientific Institute of Saigon (Indo-China), received a large number of diseased specimens of *Crotalaria juncea* from the Agricultural Station at Tuyèn-Quang (Tonkin).

From information furnished by the sender, it appears that the disease begins at the base of the plant and gradually invades the stem, causing it to wither and die. All the crops of *C. juncea* growing at the Station had been destroyed in this manner, and those of *C. usaramoensis* which had long proved resistant to the disease, began to be attacked at the beginning of September. The dry specimens that reached the Institute, did not enable a very clear idea to be formed of the appearance of the diseased plants. The cortex of the stem and roots was affected in the region of the root-collar, and in the case of some specimens where the wood beneath the cortex was discoloured and more or less brown, sections from the affected regions revealed the presence of a hyaline mycelium passing between the cells of the cortex and invading the wood vessels.

Upon stems and roots kept in a damp plate there appeared the characteristic fructifications of the following micromycetes; *Fusarium* sp., *Neocosmospora vasinfecta*, *Melanospora* sp., and subsequently, *Cucurbitaria* sp. and *Diplodia Theobromae* (?). Upon all the plants under observation only *Fusarium* sp. was found; this Deuteromycete appeared after a few days upon the sections of stem and roots containing the hyaline mycelium, and was the only fungus that developed upon the sterile cultural media upon which had been laid fragments of wood taken with every aseptic precaution, after the externally-sterilised cortex had been removed.

From the observations made on the material received *Fusarium* sp. seems to be the probable cause of the disease.

Although the author and his collaborator PHAM-TU-THIEN, have found *Fusarium* sp. and *N. vasinfecta* present at the same time upon *Crotalaria*, it is not certain that these two fructification forms belong to one species.

*N. vasinfecta* is regarded as the perfect form of *F. vasinfectum* a formidable parasite of cultivated plants and, amongst others, of the cotton-plant, in which it produces a serious disease of the root-collar.

(1) See also R. Jan. 1916, No. 123 and R. Jan. 1919, No. 729. (Ed.)

The form of *Neocosmospora* found on *Crotalaria* is morphologically similar to that parasitic on the cotton-plant, this is not the case with the two forms of *Fusarium* and the second conidial form of the *Cephalosporium* type to which they give rise

The Deuteromycete, which is suspected of being the cause of the disease attacking *Crotalaria* in Tonkin, seems to resemble in its morphological characters *Fus udum* which produces the wilt disease of *Cajanus indicus* in India

The symptoms of the disease, and the presence of *Fusarium* unaccompanied by other fungi in the woody tissues of the infected plant, indicate that this is probably an instance of a "pathological withering" identical in origin with the wilt disease described by English and American observers

No direct means of controlling this disease are known. The infection takes place in the soil and it is there that the parasite should be destroyed. Antiseptics have not given results which would warrant their use for farm crops

Good results can be obtained by a rotation of at least three courses. The intermediate crops must not consist of plants belonging to the same family as those which have to be protected by this means. The spores of the parasite remaining in the ground after the removal of the crop will eventually disappear

The best control method is undoubtedly the creation of resistant varieties. By this means particularly encouraging results have been obtained in combating diseases produced by *Fusarium* G. T.

517 ***Colletotrichum Gossypii* and *Cercospora Batatae*, Deuteromycetes new to the Philippines and Injurious to the Cotton Plant and the Sweet potato respectively.** WILLIS C. G. in *The Philippine Agriculturist*, Vol. X, No. 5, pp. 253-254, Los Baños, Laguna, December 1911

*Colletotrichum Gossypii* Southw., the metagenetic stage of *Glomerella Gossypii* (Southw.) Edg., which produces the disease known under the name of cotton anthracnose, has recently been observed on the cotton bolls at the Los Baños College of Agriculture

As this parasite has not hitherto been reported from any other part of the Philippines, the spread of the disease can probably be prevented by careful seed selection and the application of efficient quarantine measures to all cotton grown at the College

The fungus can exist in the seeds and dead tissues in the soil for a long time, and is thus very difficult to control. Cotton should not be grown indefinitely on soils infected by this disease, and as in the case of other crops, recourse must be had to a system of rotation. The danger of infection could be greatly diminished by the removal and burning of the plants after the harvest, while the spread of the disease on the stems of the host plants would be checked by taking the seed from healthy bolls only.

The presence of *Cercospora Batatae* Zimm. has also been observed at

the Los Baños College of Agriculture on the sweet potato ; this is the first time the parasite had been found on that plant in the Philippines, although it had previously been reported as doing great damage to the leaves of the sweet potato in South China. Rotation of crops might prove efficacious ; it would also be advisable to plant the sweet potato during the driest months of the year.

G. T.

518 - *Cercospora Arachidis* var. *macrospora* n. [var., a] Hyphomycete Injurious to the Pea-Nut in Lombardy, Italy. — MAFFEI L., in *Rivista di Patologia vegetale*, Year XII, Nos. 1-2, pp. 7-11. Pavia, March 29, 1922.

On a farm in the Commune of Bereguardo (Prov. of Pavia), during the second half of September 1921, round or oval spots of a dark chestnut colour, and sometimes reaching 1 cm. in diameter, were found, frequently in large numbers, on the leaves of *Arachis hypogaea*.

These spots were caused by a Hyphomycete of the genus *Cercospora*. The fructifications of this fungus developed in the spots on either surface of the leaf.

The parasite, which is new to Italy, is provisionally described as a variety (var. *Macrospora*) of *C. Arachidis* P. Henn :

It is advisable to cut off the aerial portions of the plant attacked and not to feed them to cattle or use them as manure.

G. T.

519 - The Mucoracea, *Rhizopus nigricans*, Injurious to Pumpkins, in Italy. — CIFERRI R., in *Rivista di Agricoltura*, Year XXVII, No. 13, pp. 195-196. Parma, March 31, 1922.

In 1921 a disease appeared in damp and particularly in low-lying places in the neighbourhood of Alba, which although not very wide-spread caused considerable damage here and there among the pumpkins. As soon as the pumpkins ripened, large dark, irregularly rounded spots were seen on the surface and these patches spread so extensively that the fruit became soft and was changed to a brown colour. The pulp of the pumpkins attacked was blackish-brown and the exterior of the seeds also turned brown. The mesocarp from which there exuded a hyaline, non-putrid liquid, was seen under the microscope to be greatly disorganised and invaded by a mycelium, at first hyaline, and afterwards of a greyish colour. In the mycelium were embedded black, roundish bodies (sclerotia), which helped by their number to give to the pulp its blackish colour.

Pieces of infected pumpkin when placed in a moist, warm chamber, soon became covered with a thick growth of a Mucoracea identified as *Rhizopus nigricans* Ehr., a ubiquitous, very common saprophytic fungus, known to occur as an occasional parasite.

In the case of pumpkins all the diseased fruits should be destroyed and they should not be planted in very damp places.

G. T.

520 - *Penicillium crustaceum*, the Cause of Rot in Quinces, in Italy. — CIFERRI R. in *Rivista di Patologia vegetale*, Year XII, Nos. 1-2, pp. 12-17. Pavia, March 29, 1922.

It has been noted that in the Marches, Emilia, Piedmont, and several other parts of Italy, quinces kept in damp places are liable to a chestnut-

brown rot which sometimes destroys the entire crop. At first a very small brown spot like a bruise is seen on the fruit which increases in size and becomes depressed and the tissues of the hollow part soften. At the end of a few days half the fruit is attacked by this rot and gives out the characteristic smell of organic substances in course of fermentation and decomposition. Then a felt, at first of a whitish and later of a bluish colour, makes its appearance on the depressed spot and when the rot has spread to the whole quince it becomes invested with a greenish-blue covering of different shades.

The microscopie has shown this affection to be the work of the polymorphous fungus *Penicillium crustaceum* (L.) Fr. a very common saprophyte and a facultative parasite.

The epicarp of perfectly healthy quinces when scratched by a needle infected with the conidia of this *Mucidinea* exhibits all the characteristic symptoms of the disease. If the conidia are placed on an entirely unbroken epicarp the results obtained are negative.

In order to prevent the outbreak of this disease all quinces intended for storage must be free from any lesions and the fruit should be kept in a very dry place. The quinces must not touch one another and should not be piled up in heaps.

G. T.

## WEEDS AND PARASITIC FLOWERING PLANTS

5.1 - *Striga densiflora* and *S. euphrasioides* Scrophulariaceae Parasitic on the Sugar Cane in India. IUTRA JAI CHAND in *The Agricultural Journal India* Vol. XVI Part 5 pp. 515-53 pl. 3 Calcutta 1921.

In September 1920 the sugar canes (var. Katha) grown on the banks of the Sutlej were reported to be seriously affected. On investigation it was found that the plants were severely attacked by parasites belonging to the genus *Striga* (fam. Scrophulariaceae). Two species were discovered which were subsequently identified as *S. densiflora* Benth. and *S. euphrasioides* Benth. These plants grew in great numbers from the base of the sugar-canes, hundreds being missed together on a single spot. Groups of them were also found at a certain distance from the sugar-canes, but they were connected underground with the individuals attacking the root system of their hosts. The two species of *Striga* were met with in different plantations. *S. densiflora* grew in the villages of Shergarh, Fatehgarh, Makowal etc. and *S. euphrasioides* in the fields of sugar cane and of *Indropogon Sorghum* belonging to the village of Pawat.

The presence of *Striga* plants was remarked about seven years ago in the village of Garhi in the territory of the State of Patiala and they have also been seen for three years at Shergarh and at Fatehgarh.

The sugar-canes attacked by the parasites are weakly, the leaves wither and the whole plant appears to be suffering from drought. Some of the sugar-canes are killed by the pests, whereas others are but little injured.

*Striga* has a very well developed root-system which encloses the rootlets of the sugar cane like a net. A number of suckers are put forth by the roots of the scrophulariaceae which fasten upon the rootlets of the host, and in this manner the parasite obtains all the nourishment it requires.

It is propagated only by seeds which when ripe fall in great quantities to the ground and grow at the same time as the host plant.

So far it has not been possible to make any specific recommendations as to control measures, but as in the case of other parasitic phanerogams, e. g. *Orobanche*, the development of *Striga* could doubtless be checked by pulling up the plants before the shoots have time to flower.

Since the cotton plant is not subject to the attacks of *Striga*, it is advisable whenever possible to grow cotton instead of sugar-cane in zones infested by these parasites.

G. T.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS

522 - On the Etiology of the Potato Disease known as Tip-burn in the United States (1). — EYER J. R., in *Science*, New Series, Vol. IV, No. 1416, pp. 150-151, Utica, N. Y., February 17, 1922.

Researches have been made of recent years at the Experimental Station of Pennsylvania State College with the object of determining the etiology and specific cause of the potato disease called tip-burn due to the attack of *Empoasca mali*.

The experiments were carried out in the form of a series of inoculations with aqueous and alcoholic extracts of the Rhynchote and other insects living at the expense of the potato. The inoculated plants were placed in special cages and exposed to sunlight of different degrees of intensity in order to determine how far sunlight influences the development of the disease.

The results obtained led to the following conclusions :

1) Tip-burn of the potato can be induced by means of an extract obtained by maceration of the nymphs or adult forms of *E. mali* and is transmissible by direct inoculation ; this indicates the presence of some specific substance, either inherent or of external origin and transmitted by the Rhynchote which is the actual cause of the disease.

2) The active principle of this substance is more energetic in the nymph stage of the Rhynchote.

3) The specific substance is present in the tissues of the diseased leaf after inoculation with the Rhynchote extract and can be transmitted by reinoculation to healthy plants.

4) This substance is of a definite nature and the disease cannot be induced by inoculation with extracts of insects other than *E. mali*, or by mechanical injury.

(1) See also R. Feb. 1922, No. 215. (Ed.)

5) Sunlight plays an important part in the progress of tip-burn after it has once begun, but the absence of sunlight does not prevent its appearance.  
G. T.

523 - Observations made on the Life-History of *Laspeyresia pomonella* in the Valley of the Grand Colorado. — SIEGLER E. H., and PLANCK H. K. (in collaboration with the Colorado Agricultural Experiment Station,) in *United States Department of Agriculture, Bulletin* 933, 119 pp., figs. 36, pl. 7. Washington, D. C., 1921.

*Laspeyresia pomonella* L., which is generally regarded as the most destructive enemy of apples and pears, is very common and very destructive in the Valley of the Grand (Colorado).

In view of the great losses caused by this Microlepidopteron to the fruit industry of the district, it was considered advisable that a complete study of the life history of the insect should be made, in order to obtain some basis for control experiments.

These biological investigations were begun in 1915 and continued the following year according to the scheme devised by the Bureau of Entomology of the United States in collaboration with the Colorado Agricultural Experiment Station.

The Valley of the Grand is situated in the county of Mesa on the Western slopes of the Rocky Mountains, and possesses a relatively dry climate. The day temperatures are high during the summer, but the night temperatures are comparatively low.

These conditions are so favourable to the development of *L. pomonella*, that there are two complete generations and one incomplete generation of this insect during the year.

The authors give a detailed account of the careful observations made in each of the above-mentioned years on the subjects of the duration of the chrysalis stage of pupation of caterpillars that have over-wintered; the deposition of eggs by the females coming from these caterpillars, the number of eggs laid by each female and the length of the life of the adults (both males and females) derived from the caterpillars that have over-wintered. The authors also give the most minute details of the biological investigations respecting the different stages of the first, second and third generations of the insect.

In the Valley of the Grand, the natural enemies of *L. pomonella* are of little importance.

The beetle *Tenebroides corticalis* Melsh. and the Arachnid *Coriarachne versicolor* Keys. have been reported as preying upon the caterpillars of the Microlepidopteron. An unsuccessful attempt was made to introduce a very well-known Coleopteron *Calosoma sycophanta* L. *Trichogramma minutum* Riley and *Dibrachys clisiocampi* Fitch have been found parasitic on the eggs and caterpillars respectively. The parasite *Arthrolytus apatela*. Ashmead has been obtained by breeding.

The adult individuals of *L. pomonella* hatch later in orchards than in fields, but the period of hatching is shorter in the orchards. Most of the adult insects, whether derived from the caterpillars that have hibernat-

ed or from those of the first generation, emerge during the latter part of the morning and the early hours of the afternoon, the largest number appearing as a rule between 9 and 11 a. m.

*L. pomonella* makes short local flights, but does not otherwise appear to be a migratory insect. The adults can however make continuous flights, of at least eight hundred metres, without any assistance from the wind.

The females of the microlepidopteron lay most of their eggs between late afternoon and early evening, ovipositing being especially active at dusk.

*L. pomonella* is very productive in the valley of the Grand. Three females of the first generation laid in captivity over three hundred eggs each, the largest total number of eggs laid by a single female being three hundred and sixteen, while the largest number laid in a day by one female was a hundred and fifteen.

On June 24, 1915 an orchard consisting entirely of pear-trees was examined in order to determine the cause of the leaves turning brown. It was found that the change of colour was due to the caterpillars of *L. pomonella* which, having found no fruit at their disposal, had excavated galleries in the ends of the branches of the pear-trees.

In districts where there are large numbers of *L. pomonella*, bands are very often used instead of sprays in the control of the insect. A band of material is placed round the trunk of the tree and removed about every ten days when any caterpillars that have made their cocoons under the band are destroyed.

In 1916 an experiment was made by surrounding trunks with bands of material folded in such a manner that white stripes alternated with black, and this proved that the microlepidopteron preferred to pupate under the dark portions. In must not be assumed however that the light bands are useless, for it is probable that if the caterpillar can find no better place to spin its cocoon, it will content itself with making it beneath them. In practice fruit growers have found that bands of packing cloth folded two or three times answer the purpose quite well.

The variety of the Microlepidopteron to which was given the name of *L. pomonella* L. var *simpsonii* Buck. was reared during the course of the study of the apple parasite from material collected in the open in the Valley of the Grand.

524 — Propagation of Date Palms by Cuttings favouring the Development of *Phoenicoccus Marlati*. See No 435 of this Review. (Ed.).

525 — Resistance of *Coix Lacryma Jobi* var. *mayuen* to animal Pests in the Philippines. — See No 412 of this Review

526 — *Triphleps tantilus*, a Natural Rhynchote Enemy of the Pink Cotton Boll Weevil (*Platyedra gossypiella*), in India. — BALLARD F., in *The Agricultural Journal of India*, Vol. XVI, Part 5, pp. 571-573. Calcutta, 1921.

In 1921 *Triphleps tantilus* Motsch. appeared in large numbers at Coimbatore, which confirmed the statement made in the preceding year that

this Rhynchote can live as well upon the eggs as upon the scarcely hatched larvae of the Pink Cotton Boll-Weevil. The nymphs of *Tr. tantilus* seem to attack the boll-weevil more greedily than the adult insects. A laboratory experiment has shown that the nymphs of the Rhynchote prefer the caterpillars to the eggs of *Platyedra*. It is unlikely that *Tr. tantilus* often has an opportunity of catching the *Platyedra* caterpillars in the open because as soon as they emerge from the eggs the caterpillars find their way into the nearest bolls. As, however, *Pl. gossypiella* lays its eggs in places that are much frequented by the Rhynchote, a large number must be destroyed by *Tr. tantilus*, which also lives upon other insects that are parasites of the cotton-plant. G. T.

- 527 - *Terpsiphone paradisi*, A Bird Useful to Agriculture in India. — FLETCHER T. B. and INGLIS, C. M., in *The Agricultural Journal of India*, Vol. XVI, Part 5, pp. 479-482, 1 coloured Plate, Calcutta, 1921

The authors give the descriptive characters of *Terpsiphone paradisi* (Paradise Flycatcher), and describe its habits.

This bird is found throughout India, from Afghanistan and Cashmere to Ceylon, except in the North-West to the East of the Brahmapootra, where it is replaced by *T. affinis*. It is to be met throughout the year in most of the districts of the plain, but it makes local migrations for definite periods. *T. paradisi* seems particularly common in North India. It feeds on small beetles, Diptera, Rhynchotes, Formicids and Arachnids, which it catches on the wing. It thus does great service to agriculture and for this reason is protected by law in Bengal, the Presidency of Bombay and in Burmah. It is probably protected also in Mysore. G. T.

- 528 - Insect Enemies of Rice in the Philippines. — See No. 400 of this Review.

- 529 - *Leptocorisa acuta*, a Rhynchote injurious to Rice in the Philippines (1). — UICHANCO, I., in *The Philippine Agricultural Review*, Vol. XIV, No. 1, pp. 87-125, 4 pl. Manila, 1921

It would appear from the entomological investigations that have been carried out for fifteen years by the Bureau of Science in all parts of the Philippines, and from experiments made for four years in the open by the author at Los Baños and in the neighbourhood, that the representative of the genus *Leptocorisa* which attacks rice crops in these islands may be identified as *L. acuta* Thunb, known as the "rice bug." STAL has also reported the presence of *L. varicornis* Fabr (2) in the Philippines in 1870, but judging from the descriptions given by DISTANT, the characters ascribed to *L. acuta* and *L. varicornis* do not vary sufficiently for the two insects to be regarded as belonging to distinct species.

This Rhynchote is known in many parts of the Philippines under very similar local names.

(1) See also R. Jan. 1913, Nos. 27 and 120; R. Oct. 1914, No. 971. (Ed.)

(2) See R. Oct. 1914, No. 971, and R. May 1918, No. 604. (Ed.)

*L. acuta* is widespread throughout the Philippine archipelago and causes much damage in all the rice-growing provinces. It is also known in India, China and Java — where it is commonly called “walang sangit” (1), — in Celebes, Sumatra, Borneo and others of the Sunda Isles, as well as in Australia. Very probably it exists also in Japan.

Up to the present no study has been made of the life-history of the insect in the Philippines.

During the coolest hours of the day, in the early morning and late afternoon, the nymphs and adults of *L. acuta* may be seen on the young rice panicles. Towards midday the insect seeks refuge from the intense heat of the sun and retires to the lower parts of the plants such as the leaf bases.

Although a certain number of the Rhynchotes may sometimes be found on a single rice panicle, *L. acuta* has never been observed to be gregarious during any of its developmental stages. In the rice fields the adults are usually more plentiful than the nymphs.

On the farm of the Agricultural College at Los Baños it was observed that a considerable number of *L. acuta* in all stages of development made their appearance in August, September and October, becoming numerous in November and still more plentiful in December. In the two latter months the caryopses of the rainy season rice crops are in the soft stage. In January when there is generally a drought accompanied by a very high temperature, the Rhynchote can obtain but little suitable food and its numbers therefore decrease in this and the two or three following months. Rice grown during the dry period and reaching the soft stage about March or April and during the first half of May, when it is generally very hot and dry, has been found to be less attacked by *L. acuta* than rice cultivated during the rainy season.

From the time it leaves the egg and throughout all subsequent stages the Rhyncote is capable of injuring the rice grain. The insect feeds on grains which are still in the soft stage, by inserting its sucking apparatus at the point of least resistance, namely at the conjunction of the paleae. Some days after the puncture has been made, a yellowish-brown spot is seen on the paleae, which increases gradually in size and marks the place of the wound. The grain that has been attacked does not develop normally and, though it may attain the ordinary size, is never more than an empty envelope. It is uncertain whether the subsequent growth of the caryopsis is hindered by the direct effect of the mechanical lesion produced by the insect sucking out the contents of the grain which is in course of development, or by the introduction into the grain of an enzyme or some other deleterious substance during its attack. Such seeds as shown by their external appearance that they have been attacked by *L. acuta* have a bitter or unpleasant taste which would seem to indicate that these pathological results must be due to other factors than a simple mechanical injury.

(1) See *R.* Oct. 1917, No. 978 and *R.* Feb. 1919, No. 260, (*Ed.*)

The nature of the injury wrought by *L. acuta* causes it frequently to be mistaken for the work of *Schoenobius incertellus* Walk (paddy-borer), but in this case, all the grains of the panicle are empty and of a uniform pale straw colour, whereas when a panicle has been attacked by *L. acuta*, owing to the insects' method of feeding, some only of the grains are empty, while the rest develop normally, further, the characteristic yellowish-brown spots are to be seen on the panicle at the spot where the insect has inserted its sucking apparatus.

*L. acuta* probably causes more economic damage to the rice crop in the Philippines than any other insect and the crops of rice grown during the rainy season are often diminished 50 % or more owing to its attacks.

If one rice field is planted earlier than the others in the same neighbourhood, the rice which has been first planted attracts all the individuals of *L. acuta* present in the district as soon as it has reached the soft dough stage. One planter of Bay (Laguna) lost over 70 % of his rice crop in 1918 for this very reason. Similar results occur when early varieties of rice are planted with late varieties.

From observations made at Los Baños in 1918 *L. acuta* appears to have a decided preference for certain varieties of rice. Binicol for instance is particularly liable to attack, possibly on account of its sweeter taste and characteristic smell, coupled with the fact that the paleae are not so strongly united, which facilitates the passage of the proboscis of the insect to the carvopsis.

Most of the awned varieties have proved to be immune, the awns probably acting as a protection against the intruder. Further, in these varieties, the paleae are stronger and more solidly united at the angles.

*L. acuta* is only able to injure rice grain when it is in the soft dough stage.

During the months when rice is not grown, or when it has not reached the soft stage, *L. acuta* lives at the expense of various wild plants. The insect seems, however, to prefer rice to any other of its host plants and returns to it at the earliest opportunity.

Adult individuals of the Rhynchote have been seen in the Philippines, far from any rice plants, on *Panicum flavidum* and *P. colonum* and when these Gramineae were growing together on the same ground, the insect always showed a preference for the second, no doubt because its grain is the more succulent. The nymphs of the Rhynchote have been found on *Digitaria consanguinea*. The insect has also been reported as living at the expense of *Citrus* sp. Its eggs have been found on a leaf of *C. decumana* and egg-capsules on a leaf of *Phytolacca dioica*, but experiments have shown that *L. acuta* cannot obtain a suitable food supply from either *C. decumana* or *Phyt. dioica* and that the eggs found on the leaves of these plants had probably been laid there by accident.

Subsequent experiments carried out with nineteen species of plants many of which represented the commonest weeds of the rice-fields, at Los Baños and its neighbourhood, have shown that *P. colonum*, *P. flavidum*, *P. Crus-galli*, *P. reptans* and *D. consanguinea* act as good host-plants to

*L. acuta*, for some individuals have been able to reach the adult stage, mate, and deposit eggs upon them. From the results of the experiments it appears that *Andropogon Sorghum* which is stated to be a host of *L. varicornis* in India, does not furnish food suitable to *L. acuta*. In the laboratory the *L. acuta* does fairly well on *Paspalum conjugatum*, *Panicum barbinode*, *Dactyloctenium aegyptiacum*, *P. carinatum*, *Cynodon Dactylon*, *Eleusine indica* and *Cyperus Iria*, but only until it has reached the second or third phase of the nymph stage. The author cannot at present say for certain that these latter plants are less suitable hosts from the food point of view than the 5 others mentioned above. The premature death of the nymphs might have been due to other factors and not to unsuitable nourishment.

Although the results of these experiments do not justify any definite line to be drawn between the plants upon which the Rhynchote can feed and those that are unsuited to it, they show that some wild plants are good hosts for the insect.

The author gives a detailed description of all the stages of the Rhynchote.

Under laboratory conditions it was found that the male lived from twenty-six to ninety-seven days after hatching, the average being sixty-two days; the females lived from sixty-five to a hundred and twenty-four days, the average being eighty-nine days.

The female does not attain sexual maturity until after a period varying from seven to twenty-seven days after hatching.

Mating takes place at least three times during the life of the female, and always in the morning.

Oviposition is most active from six in the evening to six in the morning.

The female lays her eggs from eleven to forty days after hatching out, the average being twenty-four days. Under laboratory conditions it has been found that the length of the laying season varies from thirty-eight to eighty-two days, with an average of sixty-five days and the female lives eleven days after the end of the laying period. The number of eggs deposited by one female in a day varies from none to twenty-three and the total number of eggs laid during the season varies from a hundred and five, to three hundred and thirty-four with an average of two hundred and twelve.

The eggs are generally deposited in one or two linear series along the median vein, on the upper surface of the leaf, at a short distance from the tip.

In the laboratory the incubation period varies from six to eight days, with an average of seven and a quarter days.

The nymph moults five times before attaining the adult stage; the complete nymph stage extends over a period of time varying from seventeen to twenty-three days, with an average of 19.6 days.

In addition to the absence of wings and of reproductive organs in the nymph and the difference in the number of segments the chief characters distinguishing nymphs from adult insects are the position of the scent

organs, which in the nymphs are situated between the third and fourth and the fourth and fifth abdominal tergite, whereas in the adults they are placed on the metathorax; and in the number of the tarsal segments, two in the case of the nymph and three in the adult insect.

The predatory Coleopteron *Cicindela sexpunctata* Fabr., which the author has never been able to find in the course of his researches, and a Hymenopterous egg parasite belonging to the family *Proctotrypidae*, have been reported as natural enemies of *L. acuta* in the Philippines.

As a result of his biological observations, the author makes some suggestions respecting the control of *L. acuta* as a starting point for further investigation.

In the first place everything should be done to increase the number of the egg parasites named, and it is necessary to import from India and other old rice-growing countries, egg-parasites as well as predatory insects that are not found in the Philippines.

The rice ought to be planted in such a way as to insure that all the crops grown during the rainy season reach the soft dough stage at about the same date in a given locality. Wherever water for irrigation is plentiful it is advisable to delay planting, so that the grain may not reach the soft dough stage before the end of January, or even as late as February.

Care should also be taken to obtain, by means of selection and crossing, types of rice that are either immune or nearly so.

Since early crops of rice planted on a small area are a great attraction to the Rhynchote, many such small plantations should be made in several places in a given district to serve as traps. After the adult insects have collected in large numbers in these small rice-fields and have laid their eggs, the plants can be burnt and in this way the adult individuals, the eggs, and any nymphs that may have developed, are destroyed. The adult insects can be attracted by pieces of putrifying meat or other suitable bait, and then killed.

They can also be captured in special long bags which are dragged across the field, as is done in India.

During the rice-growing season weeds which ripen before the crop and form hosts for the Rhynchote must be uprooted from the rice-fields. The slopes should also be cleared of all weeds. After the rice has been harvested the ground ought to be ploughed and planted with another crop, and should not be allowed to be invaded by weeds, as commonly occurs in many parts of the Philippines.

The eggs may also be collected by hand.

Insecticides acting by contact, such as kerosene emulsion, and applied by means of a knapsack sprayer may be very efficacious, especially in controlling the nymphs, which generally congregate on the panicles during the coolest hours of the day. The spraying should be carried out early in the morning, or late in the afternoon and the insecticide must only be directed against the panicles. As rice is only subject to the attack of the Rhynchote during the soft stage which lasts for about a month, the treatment must be limited to this period. The spraying should be repeated

fairly frequently during the month in order to destroy any insects that may have fallen on the ground, or otherwise escaped the previous applications.

530 - *Dysdercus* sp., a Rhynchote injurious to *Hibiscus Sabdariffa* var. *altissima* in the Federated Malay States. — See No 420 of this Review

531 - *Laphygma exempta*, a Macrolepidopteron Injurious to Sugar Cane and Maize, new to Queensland. — JARVIS, L., in *The Queensland Agricultural Journal*, Vol XVI, Part 4, pp 276-280, 1 plate Brisbane, 1921

The presence of *Laphygma exempta* Walk. was reported for the first time at Meringa near Cairns, on February 18, 1920. The larvae were already more than half-grown and had done considerable injury to the leaves of the sugar-cane and to the young maize plants.

The caterpillars were swarming in thousands over an area of about one hundred acres, but were still more numerous on the grassy strips and the edges of the fields

They carried on their depredations in the full sunlight and could be clearly seen eating up the greater part of the leaf blades of which they often left only the median vein intact.

By February 21 the larvae were fully grown. Two hundred of them were collected and put into breeding cages and after two days all the caterpillars burrowed in the soil to pupate.

The chrysalis stage lasted from seven to eleven days, the first adult insect emerged on March 1. During the following 5 days forty-one adults appeared, of which twenty-five were males and six females. Only 20.50 % of the two hundred caterpillars reached the adult stage. They were parasitised in the proportion of 33.50 % by a Tachnid, 1 % being attacked by Hymenoptera. The forty-five other caterpillars apparently succumbed to the attack of a disease of bacterial origin.

The author gives a description of the caterpillar, chrysalis, and adult, form of *L. exempta*. This Macrolepidopteron is a native of Africa, and appears never to have been observed before in the Queensland sugar-plantations.

In addition to the parasitic Tachnid already mentioned, its natural enemies are the parasitic Hymenoptera *Melopus unifestratus* Mer., and *Iphnaulax dubitorius* Fabr., and the predatory Coleopteron, *Ophonoides australis* Dej.

Should the insect do further damage, it is well to remember that the young caterpillars must be destroyed as soon as they appear. The method with a poisonous solution usually adopted is to water the grass between the bands of caterpillars and the crop to be protected.

The following formula is prescribed in Rhodesia: sodium arsenite 1 kg., liquorice, 8 kg.; water, 1 hectolitre.

When the attack is confined to a limited area, it is better to use a solution of calcium arsenite to which has been added 600 gm. of liquorice per hectolitre of water

G. T.

532 - *Cerococcus parahybensis*, a Scale-Insect found on the Coffee Plant, in the State of Parahyba, Brazil. — MOREIRA, C., in *Chacaras e Quintais*, Year XIII, in Vol. XXV, No. 1, pp. 28-30, figs. 2. São Paulo, January 15, 1922.

*Cerococcus parahybensis* Hempel, popularly known under the name of "vermelho", is most probably a parasite of the coffee-plant in the State of Parahyba, where, however, its presence was noticed only in 1921.

This scale-insect does not spread rapidly in the zone of coffee-cultivation, and is only represented there by a limited number of individuals on each plant. When this pest occurs in large numbers upon coffee-plants that have already been weakened, it furthers the destruction of the plantations, though in many cases this cannot be attributed to the insect, but is due to negligent cultivation.

The number of female insects exceeds that of the males.

The development of *Cerococcus parahybensis* is favoured by damp, and the parasites multiply greatly in the rainy season. The breeding season lasts from July to August and in October when the dry season is at its height, the insects have been found in a dying condition.

Some traces of natural enemies of this coccid have been observed.

It is impossible to employ insecticides, but the insects can be removed by the application of a hard brush or by hand.

It is necessary to cut down and burn any neglected coffee-plants that have been attacked by the parasite. The spring cultivation of the coffee plantations in the State of Parahyba should be improved, and apart from the seeds, all transport or removal of young coffee plants, or parts of plants, within the State should be prohibited. G T.

533 - *Ypsolophus marginellus*, a Microlepidopteron injurious to the Juniper, New Jersey, United States. — WEISS, H B, and LOTT, R B, in *Entomological News*, Vol XXXIII, No 3, pp 80-82. Philadelphia, March 1922

This European species has been reported in America from the State of New York, Connecticut and New Jersey, where it occurs in its larval stage upon the Juniper.

For several years *Ypsolophus marginellus* Fabr. (the Juniper web-worm) has been increasing in various parts of New Jersey, where it has done considerable damage. At the present time this Microlepidopteron is certainly to be found at Rutherford, Scotch-Plains, Springfield and New Brunswick, where it is especially common in the nursery-gardens. The caterpillar appears to confine its depredations to the leaves of *Juniperus communis* and of its varieties *aurea*, *horizontalis*, *depressa*, *hibernica* etc. The insect winters between the leaves which it fastens together by means of a web, retiring into these nests when from half to fully grown.

In the north of New Jersey, the larvae begin active life in May; they live on the more or less dry leaves, until they attain their full development when they pupate in large numbers after the middle of the month. The insect encloses itself in a white silky envelope placed between the partially eaten leaves which are covered with a web. The first adults come out towards the end of May or at the beginning of June; the largest number emerging about the middle of June. The eggs are laid singly, and quanti-

ties are usually found on the young terminal shoots, in the angle between the stem and the leaf insertion ; eggs are also sometimes laid on the shoots or stems. The incubation period has not been definitely observed : the first caterpillars, 0.5 mm. in length, were seen on July 8. On leaving the egg the larvae begin feeding on the upper epidermis of the young leaves, which become discoloured in places and finally turn entirely brown. Towards the end of July, when the caterpillars are about 2 mm. long, their webs are clearly visible. As the larvae grow, their gregarious tendency becomes more evident, and the leaves of the host-plant are more thickly enveloped in the webs. These webs first enclose the terminal shoot and then envelop the branch for some centimetres below the tip this is repeated at different points on the plant which is thus destroyed. As the season advances the webs increase in size, they contain more excrement, and the leaves wither and die. Small plants such as those of the *hibernica* variety may be entirely covered by the webs from top to bottom. There appears to be only one generation of *Ypsolophus marginellus* in the year ; the larvae grow slowly during the summer and hibernate throughout the cold season. In the spring when they again become active, the caterpillars find little green food at their disposal and appear to content themselves with dead leaves. Fifteen or more of these grubs, are found nestling in a web.

The authors give a morphological description of each stage of the *Microlepidopteron*.

As regards control, they advise treating the infested plants with lead arsenate, either in the liquid or powder form, during the last fortnight of June or the first half of July, for at that time the webs are small, thin and easily penetrated. Later on powder cannot be employed, and it is necessary to have recourse to spraying, in order to penetrate the foliage which is most closely enveloped by the webs of the insect. In the case of certain varieties of juniper, the nests containing the caterpillars can be cut off and burnt at the beginning of spring.

**Improvement in Administrative Methods  
in the Belgium Ministry of Agriculture**

by M. MAT.

*Technical officer in the Ministry of Agriculture, Brussels.*

The public services are as a rule the object of much adverse criticism. Wrongly or rightly the public accuses them of being insatiable ogres who devour a large part of the revenue ; complaints are made of the great number of officials and their inadequate output, of official delays and red tape, — in short, all possible shortcomings are laid to their charge. In Belgium they have not escaped from this chorus of criticism and attack. Are we therefore justified in concluding that the services are in fact not up to their work, or is public opinion in the wrong ? The truth, as is so constantly the case, is not to be found at either of the two extremes, but somewhere midway between them. Undoubtedly these services stand in need of certain reforms. In the absence of a well matured and harmoniously balanced programme, they seem often to be travelling without any definite direction. Their working methods are not the best adapted for modern requirements, they are insufficiently elastic and progress is too slow. The methods employed in the recruitment of officials do not always exact the required guarantees and the better elements do not receive the encouragement they deserve.

Several prominent men have recently undertaken the laborious and thankless task of analysing in detail the deficiencies of administrative systems, of investigating the causes and indicating the remedies. While in France M. FAYOL was publishing his remarkable treatise on administrative theory, M. DE VUYST in Belgium, during the German occupation, was devoting himself to similar work. Immediately following on the Ar-

mistice, M. DE VUYST was put in charge of the Second Branch of the General Administration of the Ministry of Agriculture, and so obtained an opportunity for putting a new administrative method to the test.

Before examining this method in detail it is interesting to note the mission and function of this particular Department. It has the charge of all forms of agricultural instruction and propaganda. For carrying out its duties, provincial staffs have been set up, including agricultural experts and agricultural household economy instructors and horticultural advisers, whose duties consist on the one hand of giving instruction to farmers and their wives on technical and practical questions, and on the other of keeping the Central Administration well informed as regards the general agricultural position and the forms of encouragement that should be granted.

The Administrative Department therefore forms a kind of centre receiving and coordinating reports from its outside officers, while in turn it issues commendations and advice which are the results of the examination of the questions submitted to it. Its work is obviously of extreme importance and any improvement brought about in any one of its activities cannot fail to have far reaching results.

The method introduced by M. DE VUYST into his office is based on a recognition of the 5 chief functions of administration, viz. foresight, organisation, executive work, coordination and control. These 5 factors should function simultaneously in order that the system may give the best results. The following is a description of the way in which these principles have been applied in M. DE VUYST's department.

**FORESIGHT** — Formerly, administrative bodies had no well defined programme; instead of anticipating, they rather waited on events, and their action was rather curative than preventive.

As a result of this absence of programme, the development of the different branches of a single administration was proportioned not to the real place which each should occupy in relation to the whole, but to the intelligence and activity displayed by the individual chiefs. It followed that in the long run, subordinate services tended to absorb funds, staff and accommodation out of all proportion in relation to other services of much greater importance.

There is nothing of this kind to be found in the office of M. DE VUYST, who, immediately after the Armistice, initiated and developed a programme of work extending over a period of three years and including 54 specific points. All the officials without distinction were invited to collaborate in the working out of this programme, which has been so far realised that by the end of December 1921, a new set of developments had already been planned. Included in the work that has actually been accomplished, the following are especially worthy of mention; the establishment at Ghent of an "Institut agronomique flamand"; the establishment of an "Institut supérieur d'agriculture" for young women rural workers at Laeken; the organisation of a service of agricultural household science advisers, whose duties towards the women on the farm are parallel

FIG 1 — Numbers of books and periodicals issued by the Control Library.

with those of the male State experts towards the farmers themselves; the revision of the laws with regard to agricultural education; the im-

FIG 3 — Position of intermediate and technical agricultural education in 1919 and in 1921

mediate increase in agricultural production, by means of trials of improved seed strains and fertilisers, direct appeal to the farmers, pamphlets on seed selection etc.

The new programme makes special provision for the extension of technical agricultural instruction after the school age; the establishment

of a loan service of agricultural films and slides, and the encouragement of the publication of good agricultural manuals.

This programme is posted up in all the offices, so that the officials have it constantly before their eyes.

**ORGANISATION.** — By the application of the principle of the division of labour, the instructional service has been subdivided into sections and sub-sections, each dealing with some special branch.

The composition of the staff is so regulated that if the chief has to be away, there is always some one to take his place in the office. Visitors are therefore always sure to obtain the information that they require.

The duties of each official are fixed with regard to his special knowledge, aptitude and previous experience.

The chiefs of the services carry out inspection in the country for two days in the week and are in their offices for the remaining four. Hence an inspector is always at the same time an administrator, so that he can be sure that any course of action suggested to him by his visits on the spot will be carried out in accordance with his wishes.

**EXECUTIVE WORK.** — One of the great evils from which administrative offices used to suffer consisted in the too frequent changes in the duties assigned to the officials. With the appointment of a new Chief, important modifications were introduced into existing staffs and duties were redistributed. Sometimes these changes were solely inspired by political or personal considerations. An element of permanence is important in official life by reason of its value in producing officers with special knowledge and experience. Another evil was to be found in the indifference which the chiefs too often showed their subordinates whose output they made no effort to increase. It was even fortunate if they did not actually suppress all initiative.

In the 2nd Branch of the Ministry, various methods have been adopted for increasing output. Members of the staff are given books that will be valuable to them from the point of view of their administrative and technical instruction. Among these may be mentioned. FAVOL'S "Administration industrielle et générale" — MARDEN'S "L'employé modèle" — LECENSIER'S, "Le bon sens" — Dr. LAUR'S, "Une politique agraire suisse" — "Mon Bureau" (a French review), etc.

In addition, the staff were invited to make full use of the central library of the Department, an invitation which was warmly accepted. A chart which was exhibited in the library and is reproduced here shows that the issues of new books and reviews increased from 7075 in 1920, to 11,509 in 1921 (fig. I, p. 617).

The Minister, Baron RUZETTE, in his determination to increase the efficiency of his staff, arranged for their benefit a course of agricultural administrative law and accountancy.

Promotion to the higher appointments which formerly fell to a senior member of the staff, will in the future be given only to such officials as have shown distinct evidence of knowledge and capacity.

With this object in view, an examination of the candidates for the grade of Chief of Section has been organised.

CO-ORDINATION. — In order to secure unity in action and control, and to avoid overlapping and waste of energy, the Chief of the Department holds a meeting of his colleagues every time that important problems come up for solution, or a new principle is introduced. In this way the system of water tight compartments which was so highly favoured in old time offices disappears.

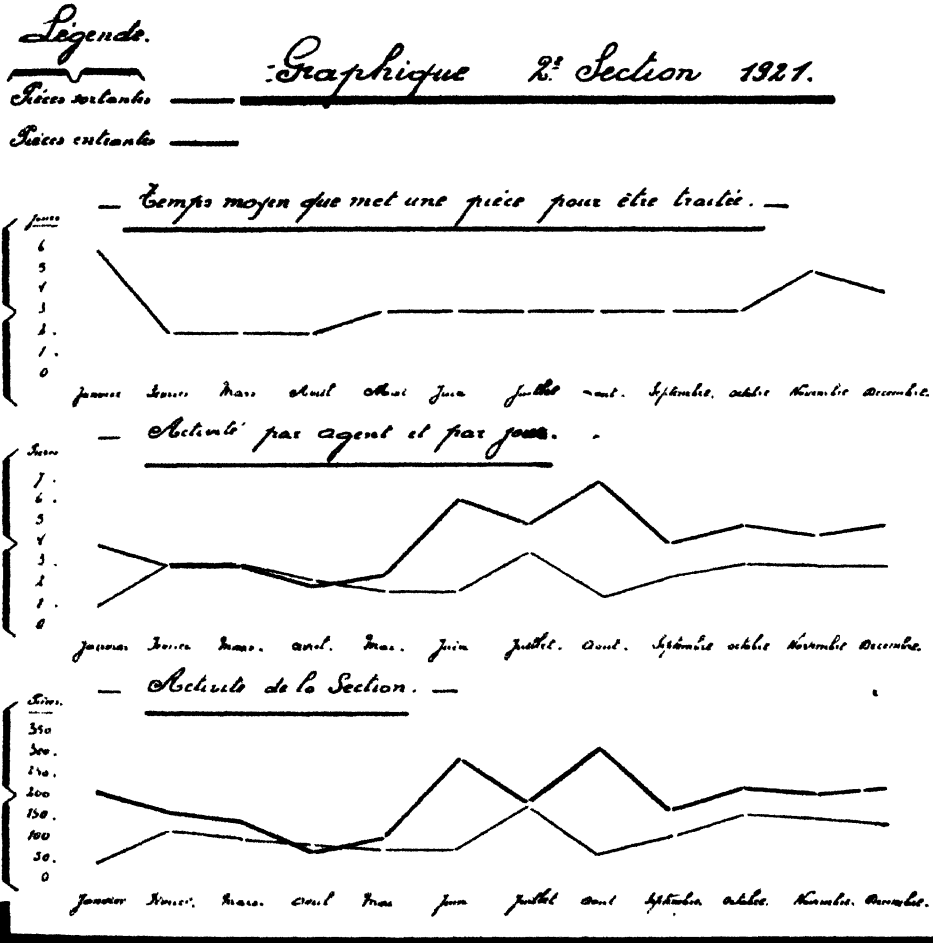

FIG. 4 — Work done by the central administrative Staff.

Apart from these occasional meetings, the Director General holds a conference at the beginning of each quarter, in his own office, in which all members of the staff without distinction take part; each is invited in turn to give an oral description of his personal share in the work and the points which he considers to be his special province. He calls attention to any shortcomings which he has noted and the reforms which should be

adopted. Similar reunions have been organised in the provinces for the members of the external staff.

**CONTROL.** — Administrative checks on the work of the different officials and services, both at the Central Office and outside, are chiefly carried out by means of charts, diagrams and graphs. By this means it is possible to obtain at a glance, without recourse to ponderous and often dusty files, an idea of the position of any given question, the points upon which activity has been specially concentrated and points that may require attention in the future. In this way, and very simply, practical effect is given to a favourite maxim of Napoleon's: "A simple sketch tells me more than a report."

These charts are of very special interest. To quote some of the most striking, fig. 2 (p. 618), shows the share of the Agricultural Budget in the General Budget for the country in 1921: viz. 23 million francs out of 3 802 million, or barely the 150th part, a share which is obviously too small when one considers the encouragement that should be given to agricultural production whose importance is higher than that of all the other industries taken together.

Fig. 2 shows also the marked disproportion which exists between the sums voted for agricultural and industrial instruction respectively: viz. 3 630 000 francs. Herein lies the explanation of the fact that industrial instruction which is the more highly favoured, is about to be substituted for agricultural instruction in several of the "écoles libres", i. e. "non-provided schools", (fig. 2, p. 618).

A third chart shows the position of intermediate agricultural and technical instruction in 1910 and 1921 (fig. 3, p. 619).

Figure 4 (p. 621) refers to the work of the staff at the central office. It shows, month by month, the average time required for the completion of a special task, the output per man and per day, and also of the section as a whole.

The diagram that deals with the State agricultural officers shows for each individual, in descending order, the number of meetings held, lessons given in schools, letters of advice to farmers, temporary courses started, and schemes of propaganda carried out. (fig. 5, p. 623).

From this instructive diagram it is possible to estimate the work performed by each individual and this information when completed by inspector's reports, makes it possible to estimate the value of each man's work. It may be noted in passing that since the establishment of this form of check the output has been nearly doubled.

Another diagram which refers to the work carried out by the women advisers on rural household science, shows at a glance the progress made in 1921 (fig. 6, p. 624).

There is also a wall map of Belgium showing the various places visited by the agricultural staff in the space of twelve months. As they are bound by their instructions to visit each commune in their district at least once a year it is easy to see how far these instructions have been carried out.

FIG 6 — Work done by the Women household economy advisers, teachers and assistants.

There are also a number of other equally interesting charts and it is certain that definite results have been obtained as a result of the adoption of the new administrative method which is here described in detail.

If all administrations, both private and public, worked on similar lines the vexed problem of reform would be in a fair way to solution.

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

- 534 - **Opening of an Autumn School for Shepherds at Rambouillet, France.** —  
FALCON, P, in *Comptes rendus de l'Académie d'Agriculture de France*, vol VIII, No. 5,  
pp 107-111 Paris, Feb. 1 1922.

AGRICULTURAL  
INSTRUCTION

In accordance with a scheme prepared by MM. DECHAMBRE, MOUSSU and the author, the Academy of Agriculture (" Académie d'Agriculture ") issued in 1920 the following recommendations for the improvement of the head of sheep :

1) Concessions of several thousand hectares should be made to colonists for sheep-rearing in North or West Africa.

2) One or more institutions for the technical study of sheep-rearing should be founded in France and North Africa : for instance in France at Rambouillet, for theoretical study : in North Africa on large holdings for practical work.

These recommendations are about to be realised, and the North African colonies to which they had been sent, have accepted them in principle.

By a decree dated 30th December 1921, the Ministry of Agriculture has decided to found a seasonal school for shepherds, as an annexe to the National Sheep Farm at Rambouillet. The period of instruction has been fixed at 14 weeks, from September 15th to December 25th for each year ; half the period to be devoted to study and the other half to practical work on the sheep-farm. The pupils, who should have attained the age of 17, and have had some experience in agriculture, will be admitted after an examination on the subjects covered by the elementary school certificate. The subjects taught will include elementary French and arithmetic ; a course of zootechnics as relating to sheep, a course in veterinary medicine, dealing especially with the ailments of sheep and a course in wood-working.

The staff of the school includes the Director, the accountant and the master shepherd of the Farm, whose respective duties are : superintendence, instruction in French and arithmetic, and practical work ; a veterinary

[Abstract No. 534]

surgeon or superintendent of studies or assistant from the Veterinary School of Alfort who will give instruction in veterinary science, and a headworkman who will be in charge of the manual training in woodwork.

F. D.

AGRICULTURAL  
RESEARCH

535 - The Botanical Station at Maison Carrée in Algeria.— TRABUT, L. and MARIE, R., in *Revue de Botanique appliquée et d'Agriculture coloniale*, Year II, No. 7, pp. 86-92. Paris, 31st March 1922.

The Botanical Station was transferred from Rouiba to Maison-Carrée in 1906. The former Station at Rouiba, founded in 1894, was utilised for ampelography and viticulture. The Botanical Station covers an area of 18 hectares. It serves as a experiment field for botanical research as applied to agriculture in North Africa. The research work is under the direction by the Botanical Department of the Central Government. The branches of enquiry followed for the last 20 years include : the introduction of useful plants ; production of new forms by crossing and selection ; testing of plants produced or introduced ; improvement of plants obtained for cultural experiments or scientific research. Experimental farms receive the plants obtained and control results by extensive culture, increase the seed output and facilitate propagation.

Every year about 100 *cereals* are sown, hybridised and selections made, among the chief objects being to strengthen resistance to rust.

The number of *forage plants* is considerable. A large number of varieties of *Medicago sativa* show very different qualities. A species of lucerne from Peru makes growth a month later in autumn, and also a month earlier in spring ; for the district along the coast with a mild winter, it seems possible to obtain a perennial or almost perennial variety. After a study of the *Medicago sativa* the Director of the Station has come to the conclusion that this cultivated variety is a hybrid between *Medicago gretula*, which grows wild in North Africa and *M. falcata*. A special feature in the wild variety is its capacity for producing rhizomes branching out from the central root ; this wild lucerne crosses readily with the cultivated variety, the results being very varied and better able to resist drought, especially in the plains. The Gramineae studied are numerous ; among the native varieties, *Phalaris* take a prominent place. A hybrid of *Phalaris nodosa*, probably a cross with *Ph. truncata*, has been named *Ph. stenoptera* Hackel ; it makes an excellent winter feed, its growth is remarkable and it affords excellent pasture and lives longer whereas the other varieties are very early affected by rust.

The Station has drawn attention to an annual and non spreading variety of the Aleppo sorghum which, under the name of " Soudan Grass ", has become a summer feed. This Graminea has been called *Holcus exiguus* by Forskall, and two varieties are cultivated : the typical and the large Soudan variety as classified by HACKEL (*Monogr. Phan.* p. 504). The first has been named " Tunis grass " by the Americans, who received it from the Botanical Station and confused Tunis with Algiers, the second, " Soudan Grass ". The botanical description of this sorghum is merely

a variety of the Aleppo sorghum, but the Aleppo sorghum is a pest among crops, whereas the small sorghum is an excellent forage plant. The Station has introduced and is growing *Pennisetum purpureum* ("Elephant Grass", "Napier Grass") from Rhodesia, a prolific feed forage plant, and *P. Meskeri*, a similar variety more resistant to drought. Japanese *Mischanthus condensatus* Hackel gives a plentiful forage yield on the experimental ground at "White Farm" in a salty soil. The small Japanese sugarcane on the same farm has yielded 140 tons of green fodder per hectare. The *Saccharum biflorum* of FORSKALL does very well for fixing extensive dunes or forests in the department of Oran.

The numerous varieties of *Trifolium alexandrinum* have been studied, and as a result of experiment a variety has been produced which is resistant to a fall in temperature below 9°, and is to-day extensively and profitably grown in North Africa.

A native Melilot classed by POMEL as *Melilotus macrostachys*, belonging to the Gussone *M. inestans* variety and identical with *M. segetalis* Brot. fl. lus. has been grown as an excellent winter feed or as a green manure for orangeries, especially those on clay soil.

Commercial varieties such as tobacco, cotton, sisal-hemp and feverfew (Spanish camomile) have been largely tested.

Since 1907, when phylloxera was noticed at Algiers, American *Vitis* has been sown especially the two varieties: *V. Berlandieri* and *V. Doaniana*.

Fruit growing is extensively carried on and there is an important plantation of fig-trees. Caprifigation has been closely studied and research work into the origin of the *Ficus Carica* is in progress.

The principal varieties of the olive-tree have been collected; they will shortly be transplanted to a special station for olive culture in favourable surroundings.

Ever since the Station was opened, research in various directions has been carried on in connection with *Citrus* and the Station has introduced the principal species and varieties for comparative study. Numerous hybrids have been produced or studied. Research work has also been done on varieties suitable for grafting.

The Japanese medlar is well represented by the varieties introduced from Japan and America and by new growths.

Numerous varieties of *Diospyrus Kaki*, *D. sinensis*, and *D. virginiana* are being studied.

*Psidium* is also represented by several productive species.

Among the *Prunus*, numerous varieties of the Japanese *P. triflora* should be mentioned, and of hybrids which find the Algerian climate very favourable; these trees, which were first introduced in 1895, are beginning to yield fine fruit, which is on sale in the principal markets of the colony and fetches a high price.

The genus *Pyrus* is largely represented by the principal wild Asiatic and European species. An important collection of cultivated varieties, mostly from the South of Europe (Portugal, Spain, Italy, Greece) has been formed.

*Malus* also provides an interesting series of Asiatic and American species and cultivated varieties.

The introduction of the Chinese *Persica Davidiana* has furnished an excellent peach-stock for grafting. The tree attains a large size at the Station and is free from gum.

A considerable area is devoted to *Opuntia*; the varieties include some bearing very good fruit with small stony seeds and others useful as forage.

The pecan (*Carya olivaeformis*) which is highly spoken of by the Station, has developed well in a rather poor clay soil; graftings have been made of the best varieties of large fruit bearers recently produced.

Forest arboriculture is represented by a collection of willows for tanning; *Salix Humboldtiana*, a very fine tree and well acclimatised, may be mentioned; poplars are also to the front, especially DODGE'S *Populus pekinensis*, which has already been reproduced. A Mexican ash (*Fraxinus Berlandierana*) shows extraordinary growth and is in leaf all the year round. *Melia Azedarach* var *umbraculifera* is also noteworthy. One of the most interesting trees is the "tipa" (*Tipuana Tipu*) from Argentina with rapid growth and dense foliage, somewhat resembling that of the *Robinia* and equal to lucerne as a feed for herbivorous animals. The *Zelkows*, the *Ulmus* and the *Celtis* form interesting groups. *Morus* is represented by the Japanese *Morus Kagaya*, a very fine tree. Finally, the authors call attention to a certain number of hybrid *Eucalyptus*:  $\times E. Trabuttii$  Vilm. (*botryoides*  $\times$  *rostrata* Trab.),  $\times E. algeriensis$  Trab. (*rostrata*  $\times$  *rudis*),  $\times E. gomphocornuta$  Trab., etc.

Similar research work is also being carried on in connection with garden crops and an important collection of artichokes has been obtained from seeds of South Italian varieties.

536 - The Forest Research Station in Denmark. - OPPERMANN, A., in *Det Forstlige Forsøgsvæsen i Danmark*, vol V, No 5, pp 391-421, 10 figs. Copenhagen, 1921.

During the period 1917-1921 (inclusive), the Department of Forest Research (1) has been entering on a new stage of development and has been re-organised on a wider basis. Thus in 1917 the post of Director became a permanent office and the staff of the station was increased. In 1921 an assistant botanist was engaged. In 1918-1919 the laboratory was established in specially built premises, to which lodgings for the Director and a steward are attached.

The Research Station possesses a nursery and a plantation; the total area covered by the Station and buildings is 5 hectares. Numerous experiments with various species of trees have been made and at the present time a number are being carried on in the nursery on different species of ordinary Danish forest-trees, as also on foreign species which seem likely to become of importance to the country. Other experiments are also being made with a view to discovering the efficacy of various forestry methods. A large number of young plants have been sent out for trial to the forest regions in different parts of Denmark.

(1) See R. 1917, No. 618. (Ed.)

On the death of Professor A. BÜHLER in 1920, the funds raised for the publication of an international bibliography on forestry, amounting to 11 422 marks, deposited at the "Wurtembergische Vereinsbank" and Tubingue, were transferred into the name of the author. G. A. B.

537 - **Two Cider-making Stations: The Fermentation Laboratory and Central Cider Brewery at Ettelbrück (Grand Duchy of Luxemburg).** — *Communicated by WAGNER, J PH President of the Société nationale d'arboriculture fruitière et d'horticulure at Ettelbrück and correspondin, member of L'Academie d'Agriculture de France*

The Fermentation Laboratory attached to Ettelbrück Agronomical Station was founded in 1899 mainly for research work on the most rational and simple processes of preparing good quality beverages from native fruits, by means of selected yeasts.

To facilitate as much as possible the use of these yeasts the laboratory is engaged each year in the culture on a large scale of selected yeasts during harvest-time and the subsequent period when the crops are being treated. The yeasts are supplied to the brewers, and merely have to be added to the musts, in the proportion of 1 litre per hectolitre, care being taken to follow the instructions, given in each parcel. The yeasts are sent in tins with a double safety-lid; this precaution is necessary because the yeast at the time of dispatch is in a high state of fermentation.

The quantities sent out increase from year to year, and have averaged from 4000 to 5000 litres for the last 10 years. This continual increase proves undoubtedly that the use of selected yeasts is really more advantageous than the old method. These yeasts undoubtedly make it possible to obtain excellent beverages, fermented quickly and regularly and keeping well.

For several years the Luxemburg fruit distilleries have also preferred to use these yeasts, experience having shown that they produce a high degree of fermentation and that the brandies thus obtained are superior, both in quality and quantity, to those made in the ordinary way.

The yeasts are in such demand for wine-making cider-making, and fruit-distilling, that when the vintage and fruit-harvest are at their height, the fermentation laboratory is scarcely able to satisfy the demands made upon it. The price of the yeasts 0 70 frs. per litre is quite moderate, so that it is within the means of all. In order to extend the use of cider among all classes of the population, members of the Arboricultural and Horticultural Society are supplied with these yeasts at a reduction of 50 % below the ordinary price, the society's funds being debited with the difference.

Before being sold to the public, the yeasts are proved in the testing-cellars of the fermentation laboratory where their properties and action are carefully studied.

In order to place within general reach the knowledge necessary for the proper utilisation of yeasts in wine and cider-making and distilling, the Government has organised special courses at the School of Agriculture, as well as conferences which are held on request by agricultural societies, arboricultural societies, etc.

As cider-making in Luxemburg was formerly much neglected and

carried out in a most rudimentary and defective manner, it was decided, with a view to encouraging the use of good cider, to make from part of the plentiful crops of roadside and other apples, a beverage that would really deserve the name of "Golden Drink". For as WARCOLLIER said in his report on "Apple Industries" ("Les Industries de la Pomme"), "the best way to render apple-crops valuable is to try to increase the consumption of cider and there is only one way of doing this, and that is, to make good cider. Cider should be a really commercial product, in other words it should be of good standard quality, keep well, be easily transported, and made to suit the taste of the customer. The number of people who would drink cider is everywhere great, but good qualities of cider are still too scarce."

The people of Luxemburg have therefore acted in full agreement with the opinion of this well known specialist in French cider-making, in founding a model establishment for this industry in close association with the scheme for the cultivation and diffusion of selected yeasts, and the encouragement of the use of good cider among all classes of the people. This establishment produces for its members 25 litres of cider ready for use from every hl of apples supplied, after fermentation and racking. It was established in 1909, through the efforts of the Luxemburg Society for the Cultivation of Fruit-trees and Horticulture and with the help of the State. It is entitled "The Central Cider-making Establishment of the Arboricultural and Horticultural Society" and has its headquarters at Ettelbrück, near the Fermentation Laboratory. The cost of installation was largely met by the State, for it renders considerable public service in the economical and proper utilisation of the fruit grown in the country.

The cider is sent to members in barrels belonging to the Establishment; the bad condition of barrels belonging to private consumers is really in most cases one of the chief causes of deterioration. The barrels of the Central Brewery are perfectly clean and free from all mustiness, etc. They are supplied free of charge to customers and must be returned in good condition.

Members of the Society have up to the present been charged a very moderate sum for the manufacture of the cider, varying for a long time from 5 to 10 centimes per litre. Owing to the increased cost of labour, the price has recently been raised to 25 centimes per litre. If the increased price of raw material be added, the Brewery can scarcely sell the cider it makes on its own account for less than 100 fcs. per hl. In addition to the cider supplied to members in exchange for their apples, is also brewed a certain quantity for members who have no fruit of their own but desire a first-class quality of cider. The small profit thus realised helps to defray part of the expenses.

The central building, where 5 or 6 persons are working during the season from October to December, and a cellar man all the year round, contains a large stock of barrels and other accessories and 7 large presses, one of which is hydraulic. This press and the crushers are worked by two electric motors.

Since 1909-1910, the Central Brewery has produced 35 000 hl. of cider for its members. It was not working during the war.

Results have shown that both the Fermentation Laboratory and the Brewery have done great service for the diffusion of a knowledge of the proper way to prepare cider and have thus fully achieved the purpose for which they were established.

No profit is realised on the Brewery and none was anticipated.

This modest co-operative undertaking is altogether different from the large cider-breweries in the cider-producing districts, as for instance, in France. There, the commercial and economic aspect is of chief importance, in the Luxembourg Establishment, on the contrary, the commercial element is left entirely out of the question and only its social and national sides are considered.

To encourage the consumption of cider its production must be made easy. Many people with or without stocks of apples would undoubtedly drink cider if they had the time, the knowledge of the necessary appliances for making, treating and preserving it but when these are absent other beverages will be used. It is precisely for such persons that the Luxembourg Horticultural and Arboricultural Society with its Central Brewery has been founded.

For the same reason it should likewise serve as a school where everyone may come and learn by seeing in practice how this wholesome beverage should be produced, treated and preserved. There would be little need of such an establishment in countries or districts where the use of cider has for centuries been habitual among the population but it may serve as an example of useful and effective propaganda and publicity.

538 - Accuracy in Experiments carried out at the Danish State Experiment Stations with Varieties and Strains of Roots. - KRISTENSEN R. K. *Udskrift for Planteavl*, Vol. XXVIII, Part 1 pp. 110-128. Copenhagen 1922.

The object of the investigation was to determine the accuracy of the experiments made at the State Experiment Stations since their foundation in comparing different varieties and strains of roots. The investigation is based on material from the experiments of 34 years and includes the results of 5014 experiments. As these results are complicated by both chance and systematic deviations, the author has worked out a special method for eliminating the systematic deviation which does not appear as an error in the experiment, and the standard deviation expressing the experimental error is computed according to a special formula based on this method (1). The experiments were made with mangolds, swedes, turnips and carrots.

(1)  $m = \sqrt{\frac{\sum (v^2)}{[p-2] (n-1)}}$  where  $m$  is the standard deviation,  $\sum (v^2)$  the sum of the squares of single deviations,  $p$  the number of varieties, and  $n$  that of places. See KRISTENSEN, R. K., *Bestemmelse af Middelfejlen ved Kombinationen af ensidige og tilfældige Ovføgelser*, *Udskrift for Planteavl* XXVIII. 1. 110-128. 1922. (1 d)

and are divided into 4 groups : I) Experiments, with varieties, 1886-1893 ; II) Preliminary experiments with strains, 1894-1899 ; III) One-year experiments with strains, 1900-1910 ; IV) Three-year experiments with strains, 1911-1919.

The experiments with mangolds were the most comprehensive. The standard deviation in the final results in these experiments, expressed in percentage of the crop was : I) 3.15 % ; II) 2.41 % ; III) 1.67 % ; IV) 0.92 %.

The constant regular decrease in the standard deviation from one group to another expresses the constant improvement in experimental methods. In the last group, the three-year experiments from 1911-1919, the standard deviation (compared with the average crop of the kind of roots in question) was :

	100 kg. dry matter per ha.	Standard Deviation	
		100 kg.	%
Mangolds . . . . .	85.6	0.79	0.92
Swedes . . . . .	79.6	0.79	0.99
Turnips . . . . .	51.7	0.73	1.41
Carrots . . . . .	66.1	1.45	2.19

The reason for the comparatively high standard deviation in the experiments with carrots may, among other causes, be found in the fact that the experiments with this root are in the main carried out on light, sandy soil where the crops are especially susceptible to the possibilities of drought, and where sand-drift sometimes occurs

G. A. B.

## CROPS AND CULTIVATION

### AGRICULTURAL METEOROLOGY

539 - Influence of Temperature and Rains on the Maize Yield in Argentina. ---  
HIESLING, N. A. in *Monthly Weather Review*, v 49, No. 10, pp. 543-548, Washington  
Oct. 1921.

Of all the factors which determine annual variations in crop yields, atmospheric changes are undoubtedly the most important, and among these the rainfall takes first place. The author, after referring to investigations already undertaken in the United States on the meteorologico-agricultural problem of maize, gives the results of experiments carried out by himself on this plant in Argentina with the object of ascertaining the influence of rainfall and temperature on its yield.

In calculating the correlation coefficients for yield, total rainfall and temperature in the different months, the author has obtained the figures set out in the following table :

*Correlation coefficients for maize yield, rainfall and temperature  
for each month of the growth period.*

	Rainfall	Temperature
October. . . . .	0.46	— 0.49
November. . . . .	0.45	— 0.47
December. . . . .	0.52	— 0.35
January . . . . .	0.46	— 0.61
February . . . . .	0.04	— 0.28
October to January	0.71	— 0.64

An examination of this table shows that the yield is to a large extent dependent on the rains of the period from October to January, and in negative correlation with the average temperature for the same period. In February, the rains no longer seem to have any influence and the effect of the temperature is accentuated the higher it is, the scarcer the yield. The effect of the rainfall for each of these months is about equal, whereas the temperature has a much greater influence in January.

On the whole, the plentiful years are those in which the rainfall is more abundant, and in those years in which the yield is poor the rainfall is correspondingly slight. On the other hand, the increase in yield is not in proportion to that of the rainfall: the yield is considerable for the first 300 millimetres, then it gradually diminishes to a maximum beyond which the effect of the rains becomes negative

G. A.

540 - **Influence of Rain on the Hay-Crop of Certain Forage-grasses at Svalöf, Sweden.** — WITTE H, in *Sveriges Utsädesföremåls Tidsskrift*, year XXXII, vol I, pp 21-57 Malmö, 1922.

Among the local agrogeological and meteorological conditions which have an influence on the growth of forage-grasses, the rains are undoubtedly the most important.

In this connection, this article gives the results of an investigation of the relation between the rainfall and the hay-crop of the following species: *Phleum pratense*, *Dactylis glomerata*, *Festuca pratensis* and *Avena elatior*.

The author has ascertained that the most beneficial rains are those which fall from the 16th April until the first cutting. The length of this period varies according to the temperature conditions and the particular species of grass

The following are the figures in the present case.

<i>Dactylis glomerata</i> . . . . .	from 53 to 75 days
<i>Avena elatior</i> . . . . .	» 51 » 80 »
<i>Festuca pratensis</i> . . . . .	» 51 » 82 »
<i>Phleum pratense</i> . . . . .	» 67 » 100 »

The results of the examination are shown in full in tables setting out the yield of these gramineae (the first cutting and aftermath) for the first and second years and also various data on the total rainfall and the number of days in each month and for different group of months on which rain fell. In table XI here reproduced are shown the total rainfall from 16th April till the first cutting, the number of rainy days for the same period and the yield in hay in kg per ha., for each species during the period 1910-1921. It proves conclusively that there is a positive connection between rainfall and crop, as will be seen at a glance from the diagram relating to *Phleum pratense*.

*Relation between rainfall and hay crop of Phleum.*

EXPLANATION :

*Ordinates* Yield in thousand of kg per hectare

*Abscissa* Year under consideration

— Hay yield per ha

- - Rainfall in mm (from 16th April till first harvest)

This connection becomes still clearer if one compares the averages for the years with similar rainfall

Group I year with slight rainfall

Group II " " medium "

Group III " " heavy "

Following the above classification we have for early gramineae

Group I 1914, 1917, 1918 and 1921 average rainfall 30 mm, number of rainy days, 11

Group II 1911, 1913 and 1915, average rainfall 65 mm, number of rainy days, 15

Group III 1910, 1912, 1916 and 1920, average rainfall 143 mm, number of rainy days, 27

and for *Phleum*

Group I 1914, 1915 and 1917, average rainfall 40 mm, number of rainy days, 16

Group II 1911, 1912, 1913 and 1921, average rainfall 112 mm, number of rainy days, 25.

Group III 1910, 1916, 1918, 1919 and 1920, average rainfall 177 mm, number of rainy days 37

A year which is dry for the early gramineae may, on the contrary, be wet for *Phleum* in consequence of the rains which fall between the two cuttings. Thus, in 1918, *Phleum* had a rainfall of 130 mm more than the early species, and yielded, on an average 70 % more (83 % in the case of *Dactylis glomerata*)

The tables which follow show as might have been expected that *Avena elatior* gives the best yield in dry years and the increase of this yield concurrently with a heavier rainfall is lower in proportion to that of the remaining three

The figures in the second table relate to the first cutting, reckoning the yield in dry years as 100

Yield in kg per ha

	Group I	Group II	Group III
1st year.			
<i>Dactylis glomerata</i>	3 910	5 640	6 610
<i>Festuca pratensis</i>	4 570	7 200	8 610
<i>Avena elatior</i>	5 200	7 310	7 940
<i>Phleum pratense</i>	4 350	5 510	7 320
2nd year			
<i>Dactylis glomerata</i>	2 680	4 800	5 840
<i>Festuca pratensis</i>	2 610	4 690	6 010
<i>Avena elatior</i>	4 120	5 760	7 560
<i>Phleum pratense</i>	2 860	5 570	5 850

There is also undoubtedly a direct connection between the yield of the aftermath and the rainfall, but it is not very easy to give the figures. The author has shown the rainfall for different periods (total fall between

Yield of the first mowing as compared with the rainfall and number of rainy days during the period from 16th April until the first cutting (Svalof, 1910-1921).

	1910	1911	1912	1913	1914	1915	1916	1917	1918	1919	1920	1921
<i>Phleum pratense</i> :												
Rainfall in mm. from 16th April			172.9	120.6	128.3	99.5	47.5	57.3	199.5	40.6	145.6	145.1
Number of rainy days.			36	29	29	22	21	17	37	10	34	45
Hay yield, kg. per ha.			4600	4510	7300	4800	4320	4890	6560	3840	6820	7140
											11460	5430
<i>Dactylis glomerata</i> :												
Rainfall in mm. from 16th April	104.8	57.2	94.0	76.0	41.8	60.3	143.7	29.6	14.5	87.0	200.7	31.3
Number of rainy days	23	17	22	12	15	16	23	7	10	20	40	12
Hay yield, kg. per ha.	5130	5660	7940	6190	5250	5080	5660	4050	3730	5560	8750	2600
<i>Festuca pratensis</i> :												
Rainfall in mm. from 16th April	113.0	59.9	138.0	77.0	42.8	60.3	172.4	29.6	15.1	104.0	200.7	31.3
Number of rainy days.	24	19	29	12	16	16	27	7	11	22	40	12
Hay yield, kg. per ha.	7200	7920	9450	7590	5390	6100	7180	4830	4290	6840	12390	3780
<i>Avena elatior</i> :												
Rainfall in mm. from 16th April.	104.8	58.9	138.0	77.0	46.8	60.3	145.5	29.6	13.5	104.0	200.7	31.3
Number of rainy days.	23	17	29	12	17	16	24	7	10	22	40	12
Hay yield, kg. per ha.	8220	8200	9180	7860	5310	5880	7620	4530	4200	536	9310	6760

the first and second cuttings ' for a period of 40 days after the first cutting ; for the fortnight before the first cutting , and for the fortnight or 30 days after the first cutting) together with the corresponding forage yield.

	Group I	Group II	Group III
<i>Dactylis glomerata</i>	100	158	189
<i>Festuca pratensis</i>	100	166	204
<i>Avena elatior</i>	100	140	166
<i>Phleum pratense</i>	100	154	179

The figures thus collected and classified, bring out, in spite of numerous exceptions, a connection between the yield of the aftermath and the rainfall at the time the first cutting both before and after. Much remains to be done before the problem can be finally solved, including experimental tests for a long series of years made under identical agrogeological conditions, careful attention being paid to all the conditions which may have any bearing on the question. G A

511 **Present Phase of Protection against Frost by means of Fumigation in the "Grand Valley" of Colorado.** — HARRICK, M. in *Monthly Weather Review* vol 17, No 1 pp 51-55. Washington Oct 1911

Ten years ago the Grand Valley of Colorado had become the centre for 'Frost Control' in the fruit belt of the United States. The head of the meteorological department at Grand Junction devoted all his energy to the development of the weather forecast service and the results were transmitted with quite remarkable regularity and rapidity.

Hundreds of horticulturists were warned in time of coming frosts and thousands of dollars were spent yearly in 'warming' orchards. Labour and fuel were at that time rather cheap and the price of fruit was high, so that expense incurred in protecting orchards against bad weather was justified. The peach, apricot, pear and apple tree plantations from Vineland and Palisade to Loma and Garmesa were artificially warmed each time the forecast indicated a temperature much below zero.

But the growers did not all join in the scheme, some because they had not the means to buy the receptacles and fuel, others because they were averse from carrying out the somewhat complicated work involved and others again from pure scepticism as to the results. When the fruit was gathered the yield was practically the same both for the growers who had not adopted protective measures and for those who had, while the latter had incurred the enormous expense of fumigating their plantations. Then came the war and with it the increased price of labour and fuel without a corresponding increase in the selling price of fruit, the fumigations were abandoned for the most part and only continued for peaches, apricots and certain varieties of early pears at Palisade in the highest part of the Valley.

In 1921 the weather was exceptionally mild in January, February and March, and thus accelerated growth, so that by the 18th of March the apricot trees were in full blossom and peach-trees were beginning to bud. From the 24th of March, however, and during the whole of April, there was a return of severe cold and the temperature fell below zero (see following Table)

*Minimum temperature registered from March to May  
in some stations of the "Grand Valley"*

Stations	March	April	May	Stations	March	April	May
Clifton	—	— 5 00	2 78	Orchard Mesa	—	— 5 00	1.67
Fruita	— 7 22	— 8 33	1 11	Palisade	— 4 44	— 4 44	3.89
Fruitvale	— 6 67	— 3 89	1 67	Pomona	— 8 33	— 6 11	1 67
Hunter	— 7 78	— 6 11	2 22	Redlands	— 6 11	— 6 11	3 33
Loma	— 8 33	— 8 33	0 00	Grand Junction	— 2 22	— 2 22	3 33

Given the advanced stage of growth these temperatures should have had a most injurious effect, instead of which the fruit yield was really very good in 1921.

From an inspection made immediately after the spring frosts it was found that only 29 growers in the neighbourhood of Palisade had had recourse to the radiators after having received warning by telephone from the Weather Bureau of the fall in temperature.

In the lower part of the Valley where fumigation is no longer practised, the Stations at Loma, Hunter, Pomona, Redlands and Orchard Mesa which were no longer needed were suppressed.

In 1921, 900 wagons of Elberta peaches and 400 wagons of pears were gathered in the Grand Valley, whereas the low temperatures which prevailed during the flowering season should have completely destroyed the crops.

Instead of fumigation, the author believes that better results could be obtained by irrigation which encourages fogs and prevents excessive falls in temperature.

512 — Clay as an Ampholyte (1). — ARRHENIUS, O. (Stockholm) in *Journal of the American Chemical Society* XLIV No 2 pp 521-524 1 fig. Easton Pa., Mar. 1921.

Soil physicists generally are aware that saline soils cause serious trouble during the filtration of extracts, and especially render the extracts cloudy or greyish. It is also known that alkaline substances tend to render the earth suspensions stable, whereas acids coagulate them. The proportion of deposit in earth suspensions is of great importance in the

(1) The so called ampholytes are amphoteric electrolytes, that is, those which contain the acid and basic groups and which consequently have at the same time an acid and a basic reaction. (1')
